## DEDICATION

This piece of work is dedicated to my children: Mary-Magdalene, Jude-Thaddeaus, Mary-Immaculate, Sarah and John-Baptiste. That it may be a source of inspiration in their growth and future endeavors.

#### Abstract

The African catfish, Clarias gariepinus (Burchell 1822) is an important species in fisheries and aquaculture in Africa. In Kenya, farmers use seeds of unknown genetic characteristics. Sourcing of brood stock for propagation at hatcheries is not controlled, with inter-basin transfer of brood stock being common. This study used 427 base pairs (bp) of mitochondrial D-loop sequence markers to determine genetic variation and population structure in 5 natural (Lakes Victoria (LVG), Kanyaboli (LKG), Turkana (LTA), Baringo (LBA) and Jipe (LJP)) and 5 farmed populations (Sangoro Aquaculture Center (SAN), Sagana Aquaculture Centre (SAG), University of Eldoret Fish Farm (UoE), Kibos Fish Farm (KIB), and Wakhungu Fish Farm (WKU)) of $C$. gariepinus collected across Kenya. Similarly, 6 microsatellite DNA markers were used to determine genetic variation in 8 populations (LVG, LKG, LTA, LBA, SAN, SAG, UoE and KIB).The 5 natural populations had higher numbers of haplotypes compared to the 5 farmed populations. Haplotype diversity values were generally consistent with haplotype numbers, with populations of higher haplotypes recording higher haplotype diversity. $88.2 \%$ of haplotypes in the 10 populations was private, with LJP showing the highest number at 12 , while WKU had the least with 1. All except LJP and LTA populations shared haplotypes, and KIB had the highest number of shared haplotypes at 8 . The 68 haplotypes identified in the 10 populations clustered into 5 groups: LVG LJP, LTA, LBA and SAG, both in the Maximum likelihood tree, and in the haplotype network. A total of 31 of 45 pair wise comparisons of the population differentiation index ( $F_{\mathrm{ST}}$ ) values were significantly different ( $\mathrm{p} \leq 0.05$ ). Microsatellite analysis showed farmed populations of higher number of alleles than natural populations, but higher observed and expected heterozygosity were recorded in the natural populations. The number of private alleles was generally uniform in the populations, although KIB and LVG had higher values. For microsatellites DNA analysis, a total of 15 out of 28 pair wise comparisons of the population differentiation index ( $F_{\mathrm{ST}}$ ) values were significantly different ( $\mathrm{p} \leq 0.05$ ), with most of the variation attributed to individual samples ( $96.72 \%$ ). All populations were in Hardy-Weinberg equilibrium, since none had significant values for exact tests of $\mathrm{H}-\mathrm{W}$ at all loci. The 8 populations grouped into 4 genetic clusters (LVG, LTA, LBA and SAG) in structure analysis, with all farmed populations grouping into the Lake Victoria population, and 3 grouping into LBA. Mean relative fecundity for the three populations was $81.9 \pm 6.0,50.8 \pm 5.6$ and $53.0 \pm 5.1 \mathrm{eggs} / \mathrm{g}$ body weight for lakes Victoria, Baringo and Kanyaboli respectively, with relative fecundity being higher in Lake Victoria than Lakes Baringo and Kanyaboli, which had similar values. Size at first maturity was higher in LBA than LVG and LKG, while a higher size at maturity was recorded in LVG compared to LKG. Therefore fecundity of fish seems to correlate with Hetereozygosity, while size at first maturity seems to be influenced more strongly by environmental factors than genetic characteristics of C. gariepinus. Water quality parameters were similar among the three sites (Lakes Victoria, Baringo and Kanyaboli) for nutrients (Total phosphorus and total nitrogen), while the physicochemical parameters varied significantly ( $\mathrm{p} \leq 0.05$ ) among sites and months of sampling. The findings suggest that LVG, LTA, LBA, LJP and SAG are genetically distinct populations, which can potentially be exploited for aquaculture. Natural populations had higher genetic variation than farmed populations, possibly due to inbreeding depression from domestication of farmed species. Farmers may increase seed production by using populations of C. gariepinus of higher genetic diversity.

## LIST OF TABLES

Table 2. 1: Countries producing at least 100 tonnes of cultured clariid catfish in 2006.

Table 3. 1: Sampling sites, coordinates, sample sizes, weights and lengths and sequence accession numbers of Clarias gariepinus samples from 10 sites in Kenya sequenced from the mtDNA D-loop control region gene. Samples from 8 (LVG, LKG, LTA, LBA, SAN, SAG, UoE and KIB) of these sites were also genotyped with 6 microsatellite DNA loci.

Table 3.2: Microsatellite DNA primers with nucleotides, range of allele size, dye colour and reference for the 6 loci used to genotype samples of Clarias gariepinus from 8 sites in Kenya. 42

Table 4.1. Genetic diversity values for samples of Clarias gariepinus from 10 different sites in Kenya inferred from mtDNA D-loop region. $\Pi$ is the nucleotide diversity and $h$ is the haplotype diversity. 51

Table 4.4: Pair wise comparisons of $\mathrm{F}_{S T}$ values of samples of Clarias gariepinus from 10 different sites in Kenya inferred from sequences of mtDNA D-loop control region. Values in bold are significantly different ( $\mathrm{P}<0.05$ ). A total of 31 of 45 pair wise comparisons are significantly different. 1 is LVG, 2 is LKG, 3 is LTA, 4 is LBA, 5 is LJP, 6 is SAN, 7 is SAG, 8 is WKU, 9 is UoE and 10 is KIB. 55

Table 4.5: Analysis of molecular variance among alleles of C. gariepinus samples from 8 different sites of Kenya. 59

Table 4.6: Proportion of membership of each pre-defined population in each of the 4 genetic clusters ( $\mathrm{K}=4$ ) inferred in samples of Clarias gariepinus from 8 different sites in Kenya genotyped at 6 microsatellite DNA loci. STRUCTURE was run with 10,000 Burn-in period and 100,000 Monte Carlo simulations.

Table 4.7: Estimates of pairwise $F_{S T}$ values, for 160 samples of Clarias gariepinus collected from 8 sites (LVG, LKG, LTA, LBA, SAN, SAG, UoE and KIB) in Kenya and genotyped at 6 microsatellite loci. Values in bold are significantly different ( $\mathrm{p}<0.05$ ). A total of 15 out of 28 pair wise comparisons are significantly different. LJP and WKU were not included in genotyping.

Table 4.8: Mean monthly relative fecundity ( $\pm$ S.E) of LVG, LBA and LKG populations of Clarias gariepinus, with respective p-values, sampled for 5 months from September 2016 to January 2017. Values with similar superscripts in a row are statistically similar.

Table 4.9: Overall mean values of nutrients (total phosphorus and total nitrogen) of Lakes Victoria, Baringo and Kanyaboli over the study period of September 2016 to January 2017.

## ACKNOWLEDGEMENT

This study was funded through the Kenya and South Africa bilateral scientific cooperation, with a research grant from the National Commission for Science, Technology and Innovation (NACOSTI) of Kenya to Prof. Romulus Abila, and the National Research Foundation (of South Africa) grant to Prof. Paul Grobler. Additional funds were provided via a PhD Science, Technology and Innovation Research grant ( $3^{\text {rd }}$ call) to James Barasa. The Flemish Inter-University Council (VLIR-UOS), Belgium, supported my short research stay at the Royal Belgian Institute of Natural Sciences, Brussels, and the University of Antwerp, to complete bioinformatics analysis and draw up manuscripts, under Dr. Erik Verheyen. Mitochondrial DNA analyses were carried out at the biosciences eastern and central Africa-International Livestock Research Institute (BecA-ILRI Hub) in Nairobi, Kenya, while Microsatellite DNA analyses were conducted at the Department of Genetics, University of the Free State, South Africa. This study also directly benefitted from the support provided to BecA-ILRI Hub by a consortium of donors.

I sincerely thank my Supervisors Prof. Romulus Abila of Maasai Mara University, Prof. Boaz Kaunda-Arara and Prof. George Dangasuk of the University of Eldoret for overseeing my research activities, and guiding the compilation of this thesis.

Special thanks to Prof. Paul J. Grobler of the University of the Free State, South Africa who played a crucial role in the implementation of the research. My fellow students at the Department of Genetics of the University of the Free State, Ms. Sinebongo Mdyogolo and Ms. Hesmari Bindeman, provided various forms of support to the microsatellite DNA component of the study.

I thank Dr. Erik Verheyen of the Evolutionary Biology group University of Antwerp and the Vertebrate Department, Royal Belgian Institute of Natural Sciences most sincerely for sponsoring my application for a short research stay in Belgium, hosting me , and guiding me in the data analyses, and illuminating the discussion of the whole study. I appreciate the support of his team at the Vertebrate Department of the Institute, especially Dr. Koen de Gelas and Dr. Zoltan Nagy, who exposed me to the use of a number of software to analyze microsatellite DNA data.

Dr. Robert Skilton, Prof. Morris Agaba, Dr. Apolonnaire Djikeng and Dr. Francesca Stomeo of BecA-ILRI Hub provided invaluable expertise during my research stint at the Hub. Moses Njahira provided invaluable technical support, and patiently guided me in learning the detailed protocols used in this study.

The late Prof. Frans Witte of the University of Leiden, The Netherlands, Prof. Ann R. Kapuscinsky and her team at the laboratory of Fish genetics, University of Minnesota, and Dr. Peter Galbusera of the Center for Conservation Biology Antwerp, provided critique that improved the initial proposal. Prof. Dominique Adriaens of Ghent University and Prof. Fillip A. M. Volckaert of Katholique University, Leuven provided useful literature on Clariid catfishes.

I also thank my colleaques, the Graduate Research Fellows using the Hub during my placement, especially Adey, Yemisrach, Ruth, Hashim, Christian, Gladiness, Patrick, Harriet, Julius and Robert. Their enthusiasm and skills on the bench gave me the energy to spend long hours in the laboratory. The International Livestock Research Institute (ILRI), the mother Institute of BecA-ILRI Hub, provided logistical support during my admission to the hub, and in the entire research period.

I thank the management of various fish farms for allowing me to sample their catfish brood stock for this study. The Beach Management Units (BMU) at Chuowe beach of Lake Victoria, Kobala in Kendu Bay, Kampi Ya Samaki of Lake Baringo and Lake Kanyaboli gave logistical support during the field sampling for catfish fecundity data, which ensured the exercise ran smoothly. William Chepkir of Kampi Ya Samaki BMU assisted in the sampling exercise at both Lakes Baringo and Victoria.

My family also takes credit, for surviving long and often turbulent periods of my absence from home.

To all of you may God bless you.

## CHAPTER ONE

## INTRODUCTION

### 1.1. Background information

Conservation of genetic diversity of a species is an important goal of conservation biology. This importance stems from the application of genetic diversity to identify distinct units of a species that require proper management (Lesica \& Allendorf, 1995). In natural ecosystems, genetic diversity influences persistence of a species in the habitat. More importantly, genetic diversity is a determinant of fitness traits of a species or population (Knaepkens et al., 2002; Blanck \& Lamouroux, 2007), although the association of genetic diversity and fitness traits is both species and trait specific (Knaepkens et al., 2002). Indeed, the theory of life history traits predicts that life history tactics adapted by a species or population is a function of the environment and genetic characteristics (Stearns, 1976). Because of this importance, therefore, genetic diversity is applied in aquaculture to identify populations suitable for use as brood stock not only to improve conservation of threatened fish species, but also increase food fish production, and livelihoods for farmers.

One such species to which information on genetic diversity may be applied to address challenges that constrain its artificial propagation and production on farms is the African catfish, Clarias gariepinus (Burchell 1822). The species is a sturdy fish, grows fast and can reach table size of 1 kg in 6-8 months (Hecht \& Britz, 1988), and has high fecundity (Hogendoorn, 1977; Owiti \& Dadzie, 1989). The fish breeds during the rainy season, where it swims in floods to spawn in inundated areas. The species feeds on a wide range of food materials and inhabits lakes, rivers and swamps (Bruton, 1988), where it plays an important ecological role as a predator (Corbet, 1961). Similarly, C. gariepinus has an extra-ordinary ability to breathe atmospheric oxygen due to the presence of a supra-branchial organ (Bruton, 1988), attributes that
make it an excellent species for aquaculture for improved food production and livelihoods especially in the rural areas in Africa. However, poor survival of juveniles in culture facilities constrain profitable culture enterprises of the species (Hecht, 1985; Hecht \& Appelbaum, 1988; Sulem et al., 2006), by limiting quantities of seeds available for expanded aquaculture and the numbers that actually grow to maturity in culture facilities. Despite several strategies being applied to address this problem (Macharia et al., 2005; Rasowo et al., 2007; Rasowo et al., 2008; Nyina-Wamwiza et al., 2010; Chepkurui-Boit et al., 2011; Magondu et al., 2011; Musa et al., 2012), high mortality of fingerlings still persists, with rates of upto $99.8 \%$ loss being reported (Hogendoorn, 1980). Recently, it has been suggested that poor quality brood stock of mixed ancestry could be contributing to poor survival of $C$. gariepinus fry at hatcheries (Barasa et al., 2014). Kenya has a natural diversity of C. gariepinus populations, some of which are unique reservoirs of genetic diversity (Barasa et al., 2014; 2016; 2017), which could be exploited in genetic improvement programmes for higher food fish production. Similarly, information on genetic diversity could be applied in monitoring of natural stocks to avoid threats such as stock mixtures (Barasa et al., 2016; 2017), overfishing (Aloo, 2003) and predation from exotic fish species (Gourdswaard \& Witte, 1997) that lower quality of brood stock through population bottlenecks.

While genetic diversity has been reported to correlate with fitness in some fish species and populations (David \& Jarne 1997; Knaepkens et al., 2002; Pojular et al., 2006; Blanck \& Lamouroux, 2007), lack of correlations is reported in other species and traits (Scott \& Koehn, 1990). These studies illustrate the complexities in heterozygosity fitness correlations (HFC) (David, 1998), because environmental factors also influence differences in fitness traits among populations of a species
(Nicola \& Almodovar, 2002). There is a dearth of information on HFC (relationship between genetic diversity and fitness traits) in tropical fish species, and it is unclear if this correlation exists in C. gariepinus as well. If so, then it may be expected that farmers would improve survival of fry at hatcheries by using brood stock from populations of higher genetic diversity. Similarly, if C. gariepinus populations exhibit differential fecundity, and if these differences correlate with genetic diversity, then farmers would gain by using brood stock of higher fecundity. This may be through higher numbers of fry obtained from a bigger batch of eggs spawned by a female, and also through higher survival of such fry. This study therefore aimed to determine genetic diversity, population genetic structure and relationship with life history traits (fecundity and size at first maturity) of selected natural and farmed populations of $C$. gariepinus in Kenya.

### 1.2. Justification of the study

Despite the importance of C. gariepinus in aquaculture in tropical areas, ranking second only to $O$. niloticus as a preferred fin fish aquaculture species in many African countries including Kenya, average annual production of the species in the country is low. According to FAO (2009), a total of 302 tonnes of C. gariepinus was produced in Kenya in 2006. This rose to 3,525 and 3,868 tonnes in 2011 and 2012 respectively (State Department of Fisheries, 2011; 2012), following the public funded National Fish Farming Enterprise Productivity Program (NFFEPP), implemented countrywide. Underlying this low annual production of farmed catfish is low survival of fry (Sulem et al., 2006), which occasions a shortage of quality seeds for expanded aquaculture enterprises. While high growth rates of fingerlings stocked in ponds or tanks are reported (Chepkirui-Boit et al., 2011; Ani-Sabwa et al., 2014), high mortality of fingerlings of 32.5 to $99.8 \%$ of the fingerlings stocked also occurs
(Kelleher \& Vincke 1976; Hogendoorn, 1980). This leads to disillusionment among farmers, and has stifled the expansion of Clarias aquaculture industry, because farmers often abandon catfish production enterprises.

Poor survival of C. gariepinus fry is attributed to poor quality diets for fry (NyinaWamwiza et al., 2010; Chepkirui-Boit et al., 2011; Musa et al., 2012), presence of predators in fry nursery systems (Sulem et al., 2006), cannibalism among siblings in fry nursery systems (Hecht \& Appelbaum, 1988; Sulem et al., 2006; Nyina-Wamwiza et al., 2010), presence of parasites and pathogens in egg incubation and fry nursery systems (Post, 1987; Rasowo et al., 2007; Magondu et al., 2011), and the use of poor quality brood stock of mixed ancestry (Barasa et al., 2014). These problems may therefore be compounded in scenarios where no genetic guidelines are applied in the management of natural stocks of C. gariepinus, sourcing of brood stock for propagation at hatcheries and general husbandry practices in both fry nursery and grow-out systems for the species at fish farms.

Information on genetic diversity and population genetic structure is now being applied in identifying fitness traits in fish species and populations (Danzmann et al., 1988; David, 1998; Knaepkens et al., 2002; Blanck \& Lamouroux, 2007; Vehvilainen et al., 2012), to determine the purity of fish brood stock for propagation (Barasa et al., 2014; 2016; 2017), to develop a genetic improvement programme for fish species targeting commercially important production phenotypes (Eknath et al., 1993; Miller \& Kapuscinski, 2003), and to identify natural populations in need of conservation because of induced population bottlenecks (Barasa et al., 2017), such as drought and overfishing (Barasa et al., 2017). While the correlation between genetic diversity and fitness has been established in some fish species (Zouros, 1987; Danzmann et al., 1988; Thelen \& Allendorf, 2001; Knaepkens et al., 2002; Blanck \& Lamouroux,

2007; Vehvilainen et al., 2012), no such correlation has been found in some aquatic animals (Scott \& Koehn, 1990), and plants (Savolainen \& Hedrick, 1995). However, a null result between heterozygosity fitness correlations in some taxa may not necessarily mean total absence of the correlations. This is because the correlation is also influenced by environmental factors (Stearns, 1976), such as age of the organism (David \& Jarne, 1997), presence of stress factors (Danzmann et al., 1988), magnitude of the stress (Audo \& Diehl, 1995), and the sample size of the species or population being analyzed (David, 1998). It is unclear if a similar relationship exists in $C$. gariepinus. If so, then C. gariepinus farmers using brood stock sourced from populations of higher genetic diversity may gain from a possible faster growth rate, higher survival and fecundity. A correlation between fecundity of the species and survival of the young has been established in Arctic charr, Salvelinus alpinus (Wallace \& Aasjord, 1984), and trout, Salvelinus fontinalis (Liskauskas \& Ferguson, 1990). It is expected that farmers using C. gariepinus populations of higher fecundity may gain from higher survival of fry at hatcheries. This would translate into higher fry from a bigger batch of eggs spawned, and possible higher survival of resultant fry. This would increase seed availability for expanded aquaculture and use as live bait for catching L. niloticus in Lake Victoria, thereby increasing food security, livelihoods for farmers, and conservation of natural populations. Similarly, a natural population of the species exhibiting higher fecundity may be expected to persist in the environment, since higher fitness reduces the risk of extinction in fishes (Feiner et al., 2017). This study investigated genetic diversity and population genetic structure in natural and farmed C. gariepinus and the influence of genetic diversity on fecundity and size at first maturity in selected natural populations in Kenya.

### 1.3. Objectives

### 1.3.1. General objective

The general objective of this study was to describe the genetic diversity and population genetic structure of C. gariepinus from different sites in Kenya, and their influence on fecundity outputs of the species.

### 1.3.2. Specific objectives

The specific objectives of the study were:

1. To determine genetic diversity of C. gariepinus from selected farms and lakes in Kenya.
2. To determine the population genetic structure of C. gariepinus from selected farms and lakes in Kenya.
3. To determine fecundity and size at first maturity of C. gariepinus from Lakes Victoria, Baringo and Kanyaboli of Kenya.
4. To determine the influence of genetic diversity on fecundity and size at first maturity of C. gariepinus from Lakes Victoria, Baringo and Kanyaboli of Kenya.

### 1.4 Hypotheses

The study is guided by the following statistical hypotheses:

Ho Natural and farmed populations of C. gariepinus from Kenya are similar in genetic diversity.

Ho Natural and farmed populations of C. gareipinus from Kenya are similar in population genetic structure.

Ho Lakes Victoria, Baringo and Kanyaboli populations of C. gariepinus have similar fecundity and size at first maturity.

Ho Lakes Victoria, Baringo and Kanyaboli populations of C. gariepinus have similar fecundity and size at first maturity.

## CHAPTER TWO

## LITERATURE REVIEW

### 2.1. The Clariidae: Evolution and adaptive radiation

Clariid catfishes are endemic to Africa, a continent that is naturally rich in biodiversity. The sheer wealth of ichthyofaunal biodiversity is for instance evident in the fact that of the 58 species of the genus Clarias, 33 occur in Africa while 25 in Asia (Na-Nakorn \& Brummett, 2009). This high abundance of species in clariidae not only reflects its importance in natural ecosystems, but even more importantly, the diversity of the genus and therefore its evolutionary ability. The family clariidae, of the order siluriformes, of Africa comprises three genera: Clarias, Bathyclarias and Gymnallabes. Heterobranchus is a non-Clarias clariid. The Asian stocks of clariidae comprise primarily the genus Clarias. Clariid catfishes evolved in the Pliocene epoch (upper tertiary period) about 7-10 million years ago (Sudarto, 2007). At that time, clariid catfishes, like most other aquatic fauna, resided in rivers and streams, the only aquatic habitats then (Nagl et al., 2000). Therefore catfishes became adapted to riverine ecosystems.

The family Clariidae is paraphyletic, consisting of several genera: Clarias, Bathyclarias, Dinotopterus, Clariallabes, Xenoclarias, and Heterobranchus (Eccles, 1992), distributed in various streams, rivers and lakes. The occurrence of these genera varies in different places. For instance, Tanzania has all the 6 genera, with Dinotopterus being endemic to Lake Tanganyika (Skelton, 1993; Mwita \& Ngwengulila, 2008). Bathyclarias is endemic to L. Malawi (Skelton, 1993).

During the Miocene period (23-5 million years ago), major vicariance events like volcanicity, shifting of tectonic plates due to seismic activity, in addition to gradual
palaeoclimatic changes gave rise to an array of habitats through rifting, elevations and depressions (Cane \& Molnar, 2001). Elevations formed mountains, rapids and plateaus; while rifting and depressions created lakes, wetlands and valleys. These activities also affected the existing channels and rivers and drainage basins, with some changing direction of flow, size of basins and the accompanying discharge, in addition to separating drainage basins that were once connected (Beadle 1974; Giddelo et al., 2002). This emergence of new habitats had profound impacts on the existing riverine catfishes. Most of the catfishes were dispersed to the new environments (Giddelo et al., 2002). Populations of catfish that once exchanged genes were separated, influencing the distribution of genetic variation. Since the new habitats were separated from each other, populations of catfish inhabiting and adapting to new environments consequently became distinct, a classical case of adaptive radiation, similar to the rise of cichlid species flocks of the Great Lakes of Africa (Greenwood, 1974; Salzburger \& Meyer, 2004). Adaptive radiation could therefore be an explanation for the high diversity in clariidae. Genetic diversity in $C$. gariepinus, for instance, is reported to be relatively high compared to other species (Galbusera, 1997; Barasa et al., 2017).

Continous palaeoclimatic changes to the aquatic habitats influenced the adaptive radiation of clariidae. Lake Victoria for instance is reported to have dried out completely 17,500 years before present (BP) and flooded 12,500 years BP (Fryer, 2001; Johnson et al., 1996), with significant implications on the adaptive ability of the resident catfish and other ichthyo-fauna. Such changes to the environment led to the evolution of adaptive mechanisms in catfish to ensure its survival, and could explain the possession of an array of important features by catfish such as the suprabranchial breathing organ. C. gariepinus survives well in habitats of low oxygen and disperses
easily due to adaptation to air-breathing, tolerates extreme desiccation, swims well and moves over land (Skelton, 1994). The species is also omnivorous and generally highly resistant to stress (Na-Nakorn \& Brummett, 2009), attributes that have made the species commercially important at the global level.

Molecular studies on C. gariepinus have shown cladistic differentiation based on different habitats. In their study phylogeography and genetic diversity of 16 populations of C. gariepinus from East Africa using the random fragment length polymorphism (RFLP) analysis, Giddelo et al., (2002) showed four groups based on a clear population structure. These included: Lake Vukoni (Lower Tana River), the eastern rift (Upper Tana River, Oloibortoto River and Lake Baringo), the western rift including the Tanzanian shield (Pangani River and Lake Jipe, Lake Edward, Luiche River, Rusizi River and Nyabugogo River) and Lake Mtera.

Phylogenetic work by Agnese and Teugels (2005), suggests that fish fauna of the family clariidae originated in Asia about 40 to 50 million years ago, moved to the Arabian plate 30 million years ago where they stayed up to around 18 million years ago, moved back to Asia before colonizing the African continent 15 million years ago. The origin of the ancestral stock of the clariidae, and this migration all took place after the split of the Pangaea into the Asian and African continents. The split occurred 160 million years ago, long before the emergence of clariidae, whose genetic divergence (12.4\%) and the oldest siluriform fossils known from the upper cretaceae about 100 million years old show the ancestral stock was much younger than 160 million years. This, coupled with molecular, parasitological and palaeontological evidence suggests that clariids originated from Asia 40 to 50 million years ago before colonizing the African continent 15 million years ago.

### 2.2. Aquaculture of Clarias gariepinus

In Africa, the genus Clarias is endemic and has 33 species. The subgenus Clarias has only two species, C. gariepinus (Burchell, 1822) and C. anguillaris (Linnaeus, 1758), of which C. gariepinus is the main farmed species (Na-Nakorn \& Brummett, 2009). Clarias anguillaris is restricted to West Africa, while C. gariepinus has a Pan-African distribution, with a natural range from the Nile to Orange River (Daget et al., 1984), and extending to the tip of North Africa and Middle East through human influence (Cambray, 2003). Because of its resilience and high adaptability, with a rare ability to walk on land when receding waters suddenly leave it stranded (Cambray, 2003), C. gariepinus has been translocated to 35 countries across the world where it plays an important role in commercial aquaculture production (FishBase, 2007). In a number of Asian countries, C. gariepinus is imported and crossed with the native Asian catfish, C. macrocephalus, for a hybrid favoured for its faster growth and higher resistance to diseases. In Thailand, for instance, a total of 7,000 metric tonnes of $C$. gariepinus was produced in 2001 (FishBase, 2003), while $90 \%$ of the total Clarias production is of hybrid catfish (C. macroephalus females * C. gariepinus males), an average of 50,000 metric tonnes annually (Na-Nakorn et al., 2004). In Malaysia, a large percentage of the 14, 693 metric tonnes of farmed Clarias produced in 2004 was C. gariepinus (Nazia et al., 2010).

In Kenya, C. gariepinus is second only to Nile tilapia, O. niloticus as a preferred fin fish aquaculture species in Kenya. It is commonly grown in earthen ponds, in polyculture with $O$. niloticus to predate against juvenile tilapias spawned, in order to avoid overpopulation of the production unit (de Graaf et al., 1996). In 2006, a total of 30 countries in Africa, Europe and Asia (Table 1) were reported to produce at least 100 tonnes of catfish each from aquaculture (FAO, 2009). This production amounted
to 300,000 tonnes valued at US $\$ 400$ million, nearly $60 \%$ of total global production of clariid catfishes (FAO, 2009). In Africa, however, the full aquaculture potential of $C$. gariepinus has not been realized, mainly due to the lack of adequate and high quality fry for stocking purposes (Sulem et al., 2006; Rasowo et al., 2008), although rising feed costs curtailed the expansion of catfish aquaculture in Southern Africa (Cambray, 2003).

Apart from stocking in ponds for grow-out as food fish, catfish fingerlings are also used as live bait for the Nile perch L. niloticus long line hook fishery in L. Victoria (Ngugi et al. 2005; Chitamwebwa et al., 2009). As a result, recent studies have focused on the improvement of fry production (de Graaf et al., 1995; Macharia et al., 2005; Rasowo et al., 2007; Ani-Sabwa et al., 2014), larval nutrition (Ngugi et al., 2005; Chepkirui-Boit et al., 2011) and testing the conditions suitable for growth of fingerlings (Ozorio et al., 2001). Notwithstanding this serious effort to increase availability of catfish fry to feed the Nile perch long line fishery, less than $2 \%$ of live bait used to catch Nile perch in L. Victoria are catfish fry (Mkumbo \& Mlaponi, 2007; Chitamwebwa et al., 2009), with the rest being haplochromines, Rastrineobola argeantae and Labeo. This illustrates the magnitude of limited supply of catfish fry in the Lake Victoria basin. Propagation of catfish at hatcheries for supply as live bait to L. niloticus fishermen has been recommended and encouraged (Kaufman \& Ochumba, 1993; Mkumbo \& Mlaponi, 2007; Chitamwebwa et al., 2009), as a way of reducing reliance on collection of live bait from natural sources, which increases pressure on indigenous threatened species like haplochromines, R. argentae and Labeo, whose methods of artificial propagation are not yet in place, and their recovery in L. Victoria after decimation by L. niloticus predation is hampered (Mkumbo \&

Mlaponi, 2007). Also, C. gariepinus fingerlings survive longer on hooks, without mortality, and so those that do not catch Nile perch in any day are still re-used.

Table 2. 1: Countries producing at least 100 tonnes of cultured clariid catfish in 2006.

| Country | Quantity (Tonnes) |
| :--- | :--- |
| South Africa | 100 |
| Cameroon | 110 |
| Italy | 115 |
| Romania | 118 |
| Togo | 200 |
| Belgium | 250 |
| Mali | 300 |
| Kenya | 302 |
| Brazil | 362 |
| Poland | 380 |
| Cambodia | 800 |
| Syria | 1,030 |
| Hungary | 1,724 |
| Philippines | 2,376 |
| Netherlands | 4,500 |
| Malasyia | 18,486 |
| Uganda | 20,941 |
| Nigeria | 51,916 |
| Indonesia | 77,332 |
| Thailand | 146,000 |
| Total | $\mathbf{3 3 7 , 3 4 2}$ |

(Source: FAO, 2009).

Propagation of adequate catfish fingerlings from hatcheries is necessary because collection of bait from the natural aquatic habitats is season-dependent, environmentally unfriendly and potentially introduces microbes into $L$. niloticus value chains. On the other hand, although induced breeding techniques in catfish have been
perfected, adequately described and are routinely practiced in many hatcheries, shortage of seeds still persists in Africa (Sulem et al., 2006; Rasowo et al., 2007) due to a variety of reasons including parasitization of catfish eggs by aquatic fungi and bacteria (Rasowo et al., 2007). It is reported that hatch rates of Clarias eggs in many hatcheries in Africa vary from 8-70\%, depending on the degree of sophistication in the particular hatchery (de Graaf et al., 1995; Macharia et al., 2005), the high fecundity of the species notwithstanding. From these studies, it is apparent that a lot of focus has been directed to addressing problems encountered in the juvenile stages of catfish, while the improvement of catfish in grow-out systems to meet the increasing demand for food fish is neglected. This could in part explain the low annual tonnage of farmed C. gariepinus from Africa. There is however renewed interest in reversing this situation through testing production systems with a view of widening the range of production systems (Imorou et al., 2007; Rasowo et al., 2008), improving the efficiency of resource use by catfish farmers (Emokaro \& Ekunwe 2009) and testing the suitability of diets in grow out units for catfish (Amisah et al., 2009). These efforts to increase the production of $C$. gariepinus from farms would be enhanced by the use of carefully genetically selected stocks of the species.

Kenya has a natural diversity of populations of C. gariepinus in inland lakes, their associated water bodies and drainage basins (Barasa et al., 2017). It is unclear which of these harbors higher growth ability, so that selection for faster growth can be narrowed down to this population to boost production from grow-out systems. The genetic purity and characteristics of cultured stocks of the species widely used on fish farms and hatcheries country wide has never been ascertained. It is possible that these stocks have undergone inbreeding and their ability to grow hampered. Fine scale molecular genetic studies of local populations of C. gariepinus would be useful in
selective breeding programs. Ascertaining genetic diversity of populations of the species is also an important first step towards developing specific C. gariepinus strains through genetic improvement, for higher production, a process that has been applied to various terrestrial animal and plant species and some aquatic species (Lind et al., 2012). Similarly, genetic diversity is a crucial indicator of population persistence against fluctuating environmental factors, conservation worth and potential for commercial exploitation of the fish resource (Lind et al., 2012).

### 2.2. Population Genetic studies on Clariidae

### 2.2.1. Mitochondrial and Microsatellite DNA Markers

Over the last two decades molecular markers have increasingly been used to measure genetic diversity in natural and aquaculture stocks of fish, generating more useful and reliable information than phenotypic markers that were used in classical genetics.

Phenotypic markers such as body dimensions, size and pigmentation are weak measures of genetic diversity in fish stocks, because these markers are environmentally influenced, polygenically inherited and have low heritabilities (Smith \& Chesser, 1981). Allozyme, microsatellite DNA and mitochondrial DNA are some of the molecular markers commonly used.

Mitochondrial DNA (mtDNA) has several advantages over nuclear DNA and therefore has been increasingly used in molecular genetic studies including population genetic studies. Apart from its very simple structure, devoid of complex introns which otherwise interrupt genes but do not code for any amino acids, mtDNA is abundant, usually 500-1,000 copies per cell as one linkage group compared to only two copies of nuclear DNA. The mtDNA is maternally inherited, since mitochondria are located in the cytoplasm and only the egg contributes cytoplasm to the zygote. Such maternally derived molecules do not recombine genetically in progeny. Therefore, unlike nuclear DNA which gets reconstituted in each generation during meiosis, the only alterations to mtDNA are accidental changes caused by mutations, copying errors or other accidents. Therefore mtDNA preserves information about ancestry. In addition, the D-loop region of mtDNA has a high rate of evolutionary change, and therefore mtDNA has become a useful marker in studying evolutionary trends in species or populations. In clariid catfishes, mtDNA has been applied to infer phylogeny (Agnese \& Teugels 2001; 2005; Mwita \& Nkwengulila 2008), taxonomy (Agnese \& Teugels 2005; Mwita \& Nkwengulila, 2008), and also genetic structure and biogeography (Giddelo et al., 2002).

Figure 2.2: Structure of Piscine mitochondrial DNA. The conserved domain preserves ancestral history, while the variable domains capture changes in DNA due to evolutionary processes. Source: Meyer, A. (1993).

Microsatellites have become important molecular markers because of its abundance in genomes, even distribution, small locus size facilitating PCR-based genotyping, codominant nature of Mendelian inheritance, and high polymorphism. High polymorphism makes microsatellite DNA markers useful in studies of parentage analysis, quantitative genetics and population genetics (Tautz, 1989). In their study of genetic variability in C. gariepinus populations from Lake Victoria, Kenya, Galbusera et al., (1996) used 10 primer sets of microsatellite DNA to show high amounts of allelic polymorphism, with the number of alleles per locus ranging from 5 to 14 , and heterozygosity ranging from 43 to $89 \%$ for the 38 samples analyzed. The number of alleles conformed to the Hardy-Weinberg equilibrium for most of the markers. Apart
from this study, which focused on using microsatellite DNA primers to study populations of C. gariepinus, Galbusera, (1997) studied genetic variation in two more populations of catfish from Kenya. These were populations from Tana River and Riakanau Dam; which were compared with populations of C. gariepinus from Cameroon, Syria, Egypt and Senegal. Therefore, only three populations of $C$. gariepinus from Kenya have been studied. It is unclear what the genetic structure and distinctness of the diversity of $C$. gariepinus resources, both wild and cultured, would be. Due to their versatility, microsatellite markers have also been used in cichlids to show genetic diversity and population structure (Abila et al., 2004; Hassanien \& Gilbey, 2005), and also levels of inbreeding and gene flow (Hassanien \& Gilbey, 2005).

### 2.2.2. Recent population genetic studies on Clarias.

The general goals of population genetic studies are to characterize the extent of genetic variation within a species and account for this variation. During the last two decades, a large amount of genotype and allele frequency data have been obtained from many fish species, mainly through protein and DNA based molecular genetic techniques. These studies have shown that most species are subdivided into distinct units that differ genetically from each other (Chakroborty \& Leimar, 1987). Genetic differences between subpopulations will evolve over time if there is little or no gene flow between them (Chakroborty \& Leimar 1987); so that restriction on gene flow may lead to genetic subdivision.

Total genetic variation in a species is a sum of between-population genetic variation and within-population genetic variation. Gene flow among sub-populations is a characteristic attribute of population genetic studies. Clarias gariepinus, being
highly predatory and omnivorous, is reported to pose a threat to native fish populations (Lal et al., 2003; Na-Nakorn et al., 2004; Senanan et al., 2004). Hybrids of catfish, popular in farming systems in Thailand and Malaysia, often escape to the wild and backcross with native Clarias macrocephalus (Lal et al., 2003; Nazia et al., 2010). Gene flow from escaped hybrids causes introgression in native stocks of C. macrocephalus, leading to poor performance in aquaculture systems. Using allozymic analysis to study genetic variation in Indian and Thailand stocks of Clarias, Lal et al., (2003) showed that C. gariepinus stocks in India were not pure, since allele frequencies departed from the Hardy Weinberg equilibrium. Since $C$. gariepinus is not found in Asia naturally, the authors attributed the presence of different gene pools in Indian stocks to mixing of stocks introduced from different farms and hatcheries, with some of the stocks having suffered drift. Clarias gariepinus from India was however shown to be different from populations from Thailand (Lal et al., 2003).

In their study on genetic impacts of hybrid catfish on native catfish populations in Central Thailand, Senanan et al., (2004) used allozymes and mitochondrial DNA to show introgression of C. gariepinus alleles into female C. macrocephalus. Thai farmers use C. gariepinus males to interbreed with C. macrocephalus females to obtain a hybrid that is popularly grown on farms every season for higher resistance to diseases and faster growth. Escaped hybrids, however, backcross with their mothers (C. macrocephalus) in the wild, so that as farmers collect $C$. macrocephalus during the next season, they do not collect pure but $C$. macrocephalus females introgressed with C. gariepinus alleles (Senanan et al., 2004). However, the levels of introgression were found to be low, so that $C$. macrocephalus female gene pools were not swamped with C. gariepinus alleles
flowing via escaped hybrids. The authors attributed the low levels of genetic introgression to limited gene flow from hybrids to $C$. macrocephalus due to relatively low number of escaped hybrids, depressed fitness of F1 and advanced generation hybrids and presence of reproductive barriers preventing extensive interbreeding between escaped hybrids and wild C. macrocephalus. Several studies have reported reduced fitness in F1 hybrids and later generation hybrids of fish from interbreeding between two genetically distinct groups, due to loss of abilities to adapt to local environments or a disruption of co-adapted gene complexes (Hallerman 2003; Miller et al., 2004). Reproductive barriers, which may be biological (e.g. low survival, low fertility, distinct reproductive timing and behaviour) or physical (e.g. preferences for distinct habitats and resources), limit interbreeding in fish (Happen \& Taylor, 2001).

Clarias macrocephalus (Gunther 1864), the main clariid species in Asia, has received a lot of attention (Senanan et al., 2004; Na-Nakorn et al., 2004), due to its commercial importance. These studies have also been prompted by the threats to genetic distinctness of the native C. macrocephalus posed by aquaculture of the exotic C. gariepinus (Na-Nakorn et al., 2004). A need has therefore arisen to elucidate the population structure of $C$. macrocephalus in order to understand its effective population size and thus the adaptation capacity of the species to cope with changing environment. More recent studies using markers of greater resolution have shown genetic variations in various populations of C. macrocephalus in Asia (NaNakorn et al., 2004; Senanan et al., 2004), and C. gariepinus (Roodt-Wilding et al., 2010; Ojiambo, 2015; Barasa et al., 2014; 2016; 2017).

Population structuring in C. macrocephalus from Thailand has been reported by NaNakorn et al., (2004), who studied 26 populations from different geographical
locations and found two genetically distinct populations, one from the southern provinces including a population from the east, and one from Chaophraya and Mekong River Basin. Distinct genetic differentiation and population genetic structuring in the African catfish, C. gariepinus, has been reported by various studies undertaken on the species from different localities on the continent (Teugels et al., 1992; Galbusera et al., 1996; Giddelo et al., 2002; Ojiambo, 2015; Barasa et al., 2014; 2016; 2017). Overall, these studies demonstrate that the family Clariidae harbours high genetic diversity and therefore has high evolutionary potential.

Due to the high diversity in the family Clariidae, taxonomy of the various groups of fauna found in the family is still largely unresolved (Teugels et al., 1992; Mwita \& Nkwengulila 2008). In the early ages, morphological and osteological features of the fish fauna were used to address questions of systematics (Teugels et al., 1992). However this 'classical' taxonomical approach was not always reliable, leading to mis-identification of some fish groups. These problems have now been overcome through molecular genetic techniques, and so molecular studies have been applied to not only accurately identify fish species and populations (Teugels et al., 1992; Lal et al., 2003; Senanan et al., 2004; Agnese \& Teugels 2005), but also elucidate both evolutionary trends (Giddelo et al., 2002; Agnese \& Teugels 2005) and phylogenetic origins (Agnese \& Teugels 2001; 2005; Mwita \& Nkwengulila 2008; Barasa et al., 2017) in the family clariidae. The study of genetic diversity in Kenyan populations of C. gariepinus would therefore be necessary to provide useful information to guide aquaculture and conservation programs.

### 2.2.3. Fecundity and size at first maturity in Clarias

### 2.2.3.1 Fecundity

Fecundity is the number of mature ova in the ovary of the female, just before spawning (Bagenal \& Tesc, 1978). Fecundity, growth and survival are important phenotypic traits in both fisheries and aquaculture because they constitute fitness traits of any fish species. They are especially important in aquaculture since they determine the choice of a species for aquaculture enterprises (Pillay, 1993), and also impact on the profitability of the enterprise. In Fisheries, the three phenotypes (fecundity, growth and survival) are applied in fisheries management, because they determine the viability and persistence of a fish species, especially in habitats that are impacted by fragmentation, pollution and overfishing. For instance, in studying fecundity of fish species, the Gonadosomatic index (GSI) and size at first maturity ( $\mathrm{L}_{\mathrm{m} 50}$ ) are usually determined, and applied to identify the breeding season of a species, when spawning activity is most intense. Knowledge of the breeding season of a species is then used to effect closed seasons for a fishery (Smith \& Walker, 2004; Njiru et al., 2006), and prohibiting fishing in identified breeding grounds for a prolonged time span for a species with asynchronous spawning (Smith \& Walker, 2004). Similarly, where overfishing is a serious problem, a fish species will attain sexual maturity earlier, grow at a faster rate, and spawn more frequently, to compensate for the high fishing mortality (Vila-Gispert \& Moreno-Amich, 2002; Blanck \& Lamouroux, 2007; Souza et al., 2015).

Table 2.2. Spatial and size-related variation in fecundity of Clarias gariepinus in Africa.

| Population | Body size (cm) | Fecundity | Mean fecundity | Reference |
| :---: | :---: | :---: | :---: | :---: |
| Lake Victoria- | 48-87 | 7,966-229,648 | 78,152 | Owiti and |
| Kenya |  |  |  | Dadzie, 1989 |
| Lake Victoria- | 50-75 | 32,000-48,000 |  | Greenwood, |
| Uganda |  |  |  | 1957 |
| Lake McIlwaine- | 45-61 | 19,422-71,510 |  | Munro, 1965 |
| Zimbabwe |  |  |  |  |
| Lake McIlwaine- | 30-70 | 4069-71,935 |  | Clay, 1979 |
| Zimbabwe |  |  |  |  |
| Lake Kariba- | 55 | 80,000 |  | Bowmaker, |
| Zimbabwe |  |  |  | 1973 |
| Lake Chamo - |  | 5,000-1,240, 000 | 337, 700 | Dadebo et al., |
| Ethiopia |  |  |  | 2011 |
| Lake Awassa |  | 8,800-650, 000 |  | Dadebo, 2000 |

Clariid catfishes naturally exhibit high fecundity. The Asian catfish, Clarias batrachus, of average length of 32 cm recorded a fecundity of 11,612 eggs in Bangladesh (Mookerjee \& Mazumdar, 1950). In the study of maturity and fecundity in C. gariepinus of Lake Victoria, Kenya, Owiti \& Dadzie, (1989) reported a mean fecundity of 78,152 eggs, with a range of 7,966 to 229,648 for fish size ranging from 48 to 87 cm total length (Table 2.2). On the Ugandan side of the lake, the species is reported to have a fecundity of 32,000 to 48,000 eggs in fish of size ranging 50 to 75 cm (Greenwood, 1957). In Lake McIlwaine of Zimbabwe, Munro, (1965) reported fecundity of C. gariepinus as $19,422,54,428$ and 71,510 eggs for fish of length $45 \mathrm{~cm}, 50 \mathrm{~cm}$ and 61 cm , respectively (Table 2.2). In the same lake, a similar investigation later reported fecundities of 4,069, 22,991 and 71,935 eggs for fish samples of $30 \mathrm{~cm}, 50 \mathrm{~cm}$ and 70 cm respectively (Clay, 1979), while the population in Lake Kariba, Zimbabwe, had 80,000 eggs for fish of 55 cm (Bowmaker, 1973) (Table 2.2). These results demonstrate that fecundity as a life-
history (lifetime pattern of reproduction and development) trait in C. gariepinus varies with the size of the fish, with bigger fish exhibiting higher fecundity than smaller fish. It also varies with a locality, where C. gariepinus of 50 cm length in Lake McIlwaine produces 22,000 eggs, while fish of almost comparable size ( 55 cm ) in Lake Kariba in the same country has a much higher fecundity of 80,000 eggs. Similar variations have been reported in C. gariepinus populations in Ethiopia: a mean fecundity of 337,700 eggs (range of 5,000 to $1,240,000$ eggs) in the Lake Chamo fish samples (Dadebo et al., 2011), and a somewhat lower fecundity ranging from 8,800 to 650,000 eggs in the Lake Awassa fish samples (Dadebo, 2000) (Table 2.2).

While differences in fecundity of C. gariepinus populations may be due to environmental differences, it may also be genetic. The influence of environmental factors on life-history traits has been demonstrated in several fish species, including brown trout (S. trutta) (Lockard, 1975; Nicola \& Almodovar, 2002), Vendace (Coregonus albula) (Karjalainen et al., 2016) and Yellow perch, Perca flavescens (Feiner et al., 2017). According to Stearns \& Crandall (1984), the evolution of lifehistory traits is constrained by trade-offs between the traits, their compatibility with other traits, the amount of genetic variation in the population and phylogenetic inertia. Therefore, while intraspecific variation in fecundity may be attributed to differences in food availability, conductivity, acidity or any other environmental variable in the habitat, it may also be due to genetic variation in the populations of the fish species (Karjalainen et al., 2016; Feiner et al., 2017). Therefore, a population of C. gariepinus, for instance, may exhibit a lower fecundity because of a lower genetic variation relative to another population of higher fecundity and higher genetic variation. The population of lower fecundity would show lower
viability and persistence in the habitat as opposed to the one of higher fecundity. Similarly, C. gariepinus of lower fecundity would be a less desirable candidate for use in aquaculture enterprises. While lower fecundity of the population may not directly help to infer survival of the individuals of C. gariepinus, the use of brood stock of the population in artificial propagation would be a disadvantage in the fewer eggs (and hatchlings) expected. There is a dearth of information on whether fecundity as a life-history strategy correlates with genetic variation of the fish population, especially in species like C. gariepinus that are economically important in the tropics. Therefore this study aimed to determine if genetic variation correlates with fecundity as a life-history trait in C. gariepinus.

### 2.2.3.3. Size at first maturity

This is the size of fish at which half the number of individuals in the population or species attains sexual maturity. It represents an important parameter in fish stock management and exploitation. Size and age at maturity influence population model estimates of sustainable harvest rates (Clark, 1991; Heino, 1998; Hard et al., 2008), and are used also in predicting the risk of overexploitation of stocks (Reynolds et al., 2005). It is important in monitoring of stocks to determine if enough juveniles in an exploited stock of fish mature and spawn (Ault et al., 1998; Jennings et al., 1998). The number of fish reaching maturity and contributing to the gene pool from which gametes are sampled for the next generation is a fitness trait for the fish population (Karna \& Panda, 2011), as it influences persistence of the species (Heino, 1998; Hard et al., 2008), especially in a changing environment.

As a fitness trait, a higher $\mathrm{L}_{\mathrm{m}} 50$ (size at maturity) would contribute to higher recruitment in the fishery, since fecundity correlates with size of fish. In
aquaculture, a higher $\mathrm{L}_{\mathrm{m}} 50$ is desirable so that a suitable size for market is still obtained from breeding fish. If the size at first maturity is low, then spawners will not grow to reach a good size for market, since energy is allocated to reproduction at the expense of somatic growth (Quince et al., 2008). Fish in populations under high predation pressure or fishing pressure mature earlier (Vrtilek \& Reichard 2016), and this reduces the asymptotic body size, since energy is reallocated from growth to reproduction (Kozlowski, 1992; Heino \& Kaitala, 1999; Quince et al., 2008). Higher fishing pressure removes the bigger fish from the fishery, and induces changes that lead to precocious parents, maturing earlier (Gross, 1996; Locham et al., 2016), and this also reduces fecundity (Hamon et al., 2000; Hamon \& Foote, 2005). Furthermore, since sexual maturation influences physiological and behavioural changes in a fish, size at first maturity is important in inferring information on fish growth, maximum size and longevity of the fish (Froese \& Binohlan, 2000). Various methods are used to estimate size at first maturity $\left(\mathrm{L}_{\mathrm{m}} 50\right)$ : linear interpolation, probit analysis, fitting of a logistic curve, or estimation from a plot of percent mature fish samples over length (Binohlan, 1998).

Table 2.3: Scale of sexual maturity stages used in the classification of Clarias gariepinus. Adopted from Hopson, 1972 and Lungayia, 1989.

| Maturity <br> stage | Description | Males | Females |
| :---: | :---: | :--- | :--- |
| I | Immature | Gonads are a pair of thin <br> threadlike transparent sacs <br> running along the dorsal wall <br> of the body cavity | Sexes indistinquishable <br> macroscopically |
| II | Developing | Testes are semi-transparent, <br> flattened and firm. Serrations <br> begin to form at one of the <br> edges. | Ovaries are clear reddish, <br> smooth, transparent and <br> light. No thickening. Small <br> ova begin to form and can <br> hardly be seen from outside |
| III | Maturing, <br> ripening | Testes begin to turn whitish, <br> widen and thicken. No milt <br> exudes when cut or <br> squeezed. Serrations are <br> more prominent. | Ovary is opaque and <br> reddish-brown. Small ova <br> are visible in a transparent <br> matrix of follicular cells. |
| IV Increases in size. |  |  |  |

In C. gariepinus, Dadebo et al., (2011) used the percentages of mature fish (P) of the length classes (L) as described by Echeverria (1987), to determine $\mathrm{L}_{\mathrm{m}} 50$, and reported length at first maturity of the species in Lake Chamo, Ethiopia as 58 cm for females and 52 cm for males. On the other hand, Wudneh, (1998) reported $\mathrm{L}_{\mathrm{m}} 50$ of
male and female C. gariepinus of Lake Tana, Ethiopia as 36 cm and 30.5 cm total length respectively (Table 2.4). In Lake Awassa of the Ethiopian Rift, C. gariepinus males matured at 33 cm while females matured at 34 cm total length (Dadebo, 2000). Similarly, Yalcin et al., (2001) reported a size at first maturity of 25.05 cm and 24.70 cm total length of females and males, respectively, of C. gariepinus in

Table 2.4. Spatial variation in size at first maturity of Clarias gariepinus populations.

| Population | Sex of fish | Size at first <br> maturity | Reference |
| :---: | :---: | :---: | :---: |
| Lake Chamo- Ethiopia | F | 58 | Dadebo et al., (2011) |
|  | M | 52 |  |
| Lake Tana- Ethiopia | F | 30.5 | Wudneh, 1998 |
|  | M | 36 |  |
| Lake Awassa- Ethiopia | F | 34 | Dadebo, 2000 |
|  | M | 33 |  |
| River Asi- Turkey | F | 25.05 | Yalcin et al., (2001) |
|  | M | 24.70 |  |
| Lake Victoria- Kenya | M | $41-45$ | Owiti and Dadzie, 1989 |
|  | F | $41-45$ |  |
|  |  |  |  |

`River Asi, Turkey. In the study of maturity and fecundity of C. gariepinus of Lake Victoria, Kenya, Owiti \& Dadzie, (1989) reported a size at first maturity of 41-45 cm for both sexes (Table 2.4). These differences in $\mathrm{L}_{\mathrm{m}} 50$ in populations of $C$. gariepinus represent the variability in fitness of the species that could arise in populations within different localities in a country or in different localities of different countries or regions. Such inter-population differences in $\mathrm{L}_{\mathrm{m}} 50$ could be attributed to environmental (food resources and water quality (Souza et al., 2015)),
the degree of fishing mortality (Wootton, 1998; Dadebo et al., 2011), and physiological or genetic differences.

Genetic influences on fitness traits such as $\mathrm{L}_{\mathrm{m}} 50$ could result from differences in population sizes, where a smaller population would suffer loss in fitness due to inbreeding, bottlenecks or genetic drift that diminishes genetic variability and the evolutionary potential of the species. However, for populations whose sizes are comparably large, and therefore panmictic, genetic influences on fitness would result if levels of genetic diversity are different. There is a dearth of information on genetic influences on fitness traits in fish species, and since correlations of genetic variation and fitness in fish are often species and trait-specific (Knaepkens, et al., 2002), the correlations warrant investigation, especially for tropical species like $C$. gariepinus. Size at first maturity has been investigated in many fish species, both marine (Hutchings \& Jones, 1998; Agembe, 2012; McBride et al., 2013; Tampubolon et al., 2014) and fresh water (He \& Stewart, 2001; Njiru et al., 2006; Blanck \& Lamouroux, 2007; Joanna et al., 2011; Maithya et al., 2012), which reflects its importance in the management of fisheries resources globally. In most of these studies, size at first maturity is presented as a parameter which influences fitness traits of growth, survival and fecundity or reproductive effort (Blanck \& Lamourou, 2007; Souza et al., 2015).

When a fish acquires sexual maturity, a substantial energy budget is invested into reproduction, by developing gametes and the actual reproduction events or reproduction in future (Quince et al., 2008; Sibly et al., 2013; Souza et al., 2015). This conversion of energy into reproductive effort limits amount of energy available for somatic growth and survival which are necessary for future reproduction of the species (Link \& Burnnett, 2001; Souza et al., 2015). Therefore, in normal
physiological activities of a fish species, the allocation of energy for reproduction is a trade-off with growth, survival and body condition (condition factor) (Souza et al., 2015), which are key fitness traits in fisheries and aquaculture. Studies report that fitness traits or life-history strategies are influenced by demographic, physiological and genetic factors (Vila-Gispert \& Moreno-Avich, 2002; Blanck \& Lamouroux, 2007), which consequently determine energy and biomass allocation in particular fish species (Vila-Gispert \& Moreno-Avich, 2002; Blanck \& Lamouroux, 2007; Souza et al., 2015).

If size at first maturity of a fish species is a function of genetic factors for instance, phenotypic variation would be observed in populations of the species of different genetic characteristics. Therefore one population would present fish that sexually mature earlier or at a smaller size, while in another population, fish would mature latter or at a bigger size. The consequences of these phenotypic manifestations would be reduced viability and persistence by a population of smaller size at first maturity, and a higher viability in one of bigger size at maturity. Although these correlations are rarely tested in aquaculture, a species with a smaller size at maturity may present poor growth rates, survival and food conversion rates in aquaculture units, since a substantial amount of energy is invested in reproduction. The best example of this is $O$. niloticus, whose size at first maturity appears to be a function of the environment. In the wild, the species reaches sexual maturity at 2-3 years old at a size of 30 to 40 cm (Moreau et al., 1986; Kolding, 1993; Njiru et al., 2006), but in aquaculture units, $O$. niloticus reaches sexual maturity at 2 to 3 months old, when they are just about 12 cm long and weight of 20g (Bolivar et al., 1993; Egna \& Boyd, 1997).

## CHAPTER THREE

## MATERIALS AND METHODS

### 3.1. Study sites

Samples of C. gariepinus were collected from a total of 10 sites across Kenya, which included 5 lakes (Victoria, Kanyaboli, Turkana, Jipe and Baringo) and 5 public fish farms, (Sangoro Aquaculture Center, Sagana Aquaculture Center, University of Eldoret Fish Farm, Kibos Fish Farm, and Wakhungu Fish Farm) (Figure 3.1). Samples from all the 10 sites were used in the mitochondrial DNA analysis (Table 3.1), while samples from only 8 sites (Lakes Victoria, Kanyaboli, Turkana and Baringo, and four fish farms: Sangoro Aquaculture Center, Sagana Aquaculture Center, University of Eldoret Fish Farm and Kibos Fish Farm) of the 10 sites were used in the microsatellite DNA analysis (Table 3.2).

### 3.1.1. Lake Victoria

This is the largest freshwater lake in Africa, and the second largest in the world (LVBC, 2011), with a drainage basin of $180,000 \mathrm{~km}^{2}$. The lake is a transboundary resource, with a total surface area of $69,000 \mathrm{~km}^{2}$, shared between Kenya, Uganda and Tanzania, and lies at latitudes $2.5^{\circ}$ and $1.5^{\circ} \mathrm{N}$ and longitudes $32^{\circ}$ and $35^{\circ} \mathrm{E}$. Sampling for $C$. gariepinus was done on the Kenyan portion of the lake, at Kobala beach which lies at $34^{\circ} 38^{\prime} \mathrm{E}$ and latitudes $0^{\circ} 21^{\prime} \mathrm{S}$, Chuowe area of Kendu Bay in Homa Bay County

### 3.1.2 Lake Turkana

It is an endorrheic lake drained mainly the Omo River from Ethiopia, and the seasonal Turkwell River from the Kerio Valley. It lies at $3^{\circ} 37^{\prime} \mathrm{N} 36^{\circ} 0^{\prime} \mathrm{E}$, within the eastern arm of the Rift Valley. It is the world's largest desert lake, with a surface area of $68,680 \mathrm{~km}^{2}$ at an altitude of 360 m above sea level. Fish samples of C. gariepinus were collected from beaches of the Ferguson Gulf, which is highly fertile, because of high total alkalinity, located at Kalokol township of Lodwar, Turkana County.

Figure 3.1: Map of Kenya with the location of 10 sampling sites for samples of $\boldsymbol{C}$. gariepinus. Natural populations were collected from 5 lakes: Lakes Victoria (LVG), Kanyaboli (LKG), Turkana (LTA), Baringo (LBA) and Jipe (LJP), represented on the map in light blue colour. Farmed populations were collected from 5 fish farms: Sagana Aquaculture Center (SAG), Sangoro Aquaculture Center (SAN), University of Eldoret Fish Farm (UoE), Kibos Fish Farm (KIB) and Wakhungu Fish Farm (WKU), represented by a star in deep blue colour. Sampling for fecundity was done on fish samples from Lakes Victoria (LVG), Baringo (LBA) and Kanyaboli (LKG). Source: Author, 2017.

### 3.1.3. Lake Kanyaboli

It is a satellite of Lake Victoria, located in the extensive Yala swamp in Siaya County. It has a surface area of $10.5 \mathrm{Km}^{2}$, a maximum depth of 4.5 m and is fringed by dense papyrus vegetation (Plate 1), bordered on the north by River Nzoia and to the south by River Yala. The massive papyrus (Cyperus papyrus and the sedge Echinocloa) swamp separates the lake from L. Victoria and apparently prevents any exchange of fish between the two lakes. It lies at latitudes $00^{\circ} 04^{\prime} 30^{\prime \prime} \mathrm{N}$, and longitudes $34^{\circ} 09^{\prime} 36^{\prime \prime} \mathrm{E}$, and at altitude of 1140 m above sea level.

Plate 3.1: Dense papyrus fringe around Lake Kanyaboli at Kadenge beach, one of the sampling sites for Clarias gariepinus for studies on both genetic analyses and fecundity. Water at the fore forms the channel from the landing beach to the lake. Source, Author, 2012.

Table 3. 1: Sampling sites, coordinates, sample sizes, weights and lengths and sequence accession numbers of Clarias gariepinus samples from 10 sites in Kenya sequenced from the mtDNA D-loop control region gene. Samples from 8 (LVG, LKG, LTA, LBA, SAN, SAG, UoE and KIB) of these sites were also genotyped with 6 microsatellite DNA loci.

| Site | Population Code | Coordinates | Sample size | Range in weight (g) | Range in length (cm) | GenBank sequence Accession numbers |

### 3.1.4 Lake Baringo

It has a surface area of $130 \mathrm{~km}^{2}$ located at $0^{\circ} 38^{\prime} \mathrm{N} 36^{\circ} 05^{\prime} \mathrm{E}$ and altitude of 970 m above sea level. It is drained by several rivers, including Ol Arabel, Mukutan, Endao and Chemeron which are seasonal, and Molo, and Perkerra which are perennial. The Lake loses water through underground seepage (Onyando et al., 2005), which together with surface evaporation because of high temperatures, help to maintain the waters fresh.

### 3.1.5 Lake Jipe

Lake Jipe, with a surface area of $30 \mathrm{~km}^{2}$ lies at an altitude of 705 m above sea level, and at $3^{\circ} 35^{\prime} \mathrm{S} 37^{\circ} 45^{\prime} \mathrm{E}$. It straddles both Kenya and Tanzanian borders, being situated to the south east of Kilimanjaro in Taita Taveta County and in the southern Kilimanjaro region of Manga district, Tanzania. The Lake is fed by River Lumi, and outflow is via the Pangani River in Tanzania. It is colonized by mainly $O$. niloticus and C. gariepinus.

### 3.1.6 Sagana Aquaculture Center

Located at Sagana township of Kirinyaga county 106 km north of Nairobi, Sagana Aquaculture Center lies at $0^{\circ} 39^{\prime} \mathrm{S} 37^{\circ} 12^{\prime} \mathrm{E}$ and altitude of $1,231 \mathrm{~m}$ above sea level. The Center was started in 1948 by the British colonial Government to support aquaculture development in the country, and has 109 operational earthen ponds, of which 72 are for research and the rest for fish production. The Center also has a hatchery unit for propagation and nursery of $O$. niloticus, C. gariepinus and $C$.
auratus. Water supply is harnessed from the neighboring Ragati River, and flows naturally by gravity.

### 3.1.7 Sangoro Aquaculture Center

It is situated at $0^{\circ} 30^{\prime} \mathrm{N} 0^{\circ} 45^{\prime} \mathrm{N}$ in the lower plains of Nyakach along the Sondu Miriu River at Nyakwere. It produces mainly O. niloticus, C. gariepinus and C. auratus. It has a total of 40 ponds covered with pond liners and a hatchery for propagation, nursery and rearing of the fish.

### 3.1.8 University of Eldoret (UoE) Fish Farm

It is located at the University of Eldoret, developed by the Department of Fisheries and Aquatic Sciences in 2003, for teaching, research and fish production. It lies at $0^{\circ}$ $57^{\prime} \mathrm{N} 35^{\circ} 30^{\prime} \mathrm{E}$, and altitude of $2,180 \mathrm{~m}$ above level on a flat land along the Eldoret-Ziwa-Kitale road. Its water supply is from a reservoir created by the surrounding extensive Marura swamp. It has a total of 42 earthen ponds of different sizes, and a modern hatchery for propagation and nursery rearing of C. gariepinus and $O$. niloticus and C. auratus.

### 3.1.9 Kibos Fish Farm

Owned by the Lake Basin Development Authority (LBDA), Kibos Fish Farm lies at $0^{\circ} 04^{\prime} \mathrm{S} 4^{\circ} 48^{\prime} \mathrm{E}$, on the outskirts of Kisumu city. It has a total of 13 ponds, and an outdoor hatchery, where artificial propagation of C. gariepinus is done. The farm also grows $O$. niloticus in earthen ponds.

Plate 3.2: One of the earthen ponds at Kibos Fish Farm used to rear Clarias gariepinus. Source: Author, 2012.

### 3.1.10 Wakhungu Fish Farm

It is located at $0^{\circ} 30^{\prime} \mathrm{N} 0^{\circ} 00^{\prime} \mathrm{E}$ in Busia County, and has a total of 15 ponds, in which C. gariepinus, O. niloticus and C. auratus are reared. It has a modern hatchery for propagation and nursery of C. gariepinus.

### 3.2. Collection of fin clips

During field work, fin clips were collected from samples of C. gariepinus for use in the laboratory as the source of DNA. For natural populations, fish samples were taken from fishermen's landings, while for fish farms, samples were taken from the rearing ponds. Sampling exercise was done between January to April 2012 for all the sites, except for Lake Jipe, where sampling was done in February 2014. Sample sizes ranged from 23 to 32 (Table 3.1). At each sampling site, samples of catfish were obtained and approximately 25 mg piece of fin tissue clipped off using a clean pair of scissors. The fin clip was preserved in $95 \%$ ethanol in a sterile cryovial (eppendorf) tube $(1.5 \mathrm{ml})$. Each tube was clearly labeled with the specimen number, and taken to the laboratory for molecular analysis.

### 3.3. DNA extraction

From each fin tissue, DNA was extracted using the Invitrogen Purelink genomic DNA extraction kit using the Manufacturer's protocol, as used in Barasa et al., (2014; 2016; 2017). DNA extraction from fin clips of the African catfish was done using the protocol by the Invitrogen PureLink genomic DNA mini kit. 25 mg of fin tissue was placed in a clean vial and $180 \mu \mathrm{l}$ of genomic digestion buffer added. Then $20 \mu \mathrm{l}$ of proteinase K enzyme was added to the vial and incubated at $55^{\circ} \mathrm{C}$ for 2 hours with vortexing every 30 minutes. RNase enzyme was added, vortexed and incubated at room temperature. On a cold or rainy day, incubation was done at $37^{\circ} \mathrm{C}$ for 20 minutes to allow for complete enzyme action. The sample was centrifuged for 3 minutes at $14,000 \mathrm{rpm}$ to remove any impurities. $200 \mu \mathrm{l}$ of Genomic lysis or binding buffer was added to sample, and then $200 \mu$ of absolute alcohol added, vortexed for homogenization.

The lysate was transferred to a spin column and centrifuged for 1 minute at 14,000 rpm. The flow throw was discarded, spin column transferred to a collection tube, 500 $\mu \mathrm{l}$ of wash buffer 1 added and spinned for 1 minute at $14,000 \mathrm{rpm}$. The flow through was discarded and spin column transferred to a new collection tube, $500 \mu \mathrm{l}$ of wash buffer 2 added and spinned for 1 minute at $14,000 \mathrm{rpm}$. The flow through was discarded and the spin column transferred to a new collection tube. This was spinned again for 11 minute at $14,000 \mathrm{rpm}$ to wash off any excess alcohol, which would otherwise interfere with downstream manifestation of DNA. The spin column was transferred to a clean microcentrifuge tube $(1.5 \mathrm{ml})$ and eluted with $50 \mu \mathrm{l}$ of Genomic elution buffer. The purity of eluted DNA was checked by nanodrop spectrophotometry (on a nanodrop spectrophotometer 2000), where the yield of DNA was also quantified ( $\mathrm{ng} / \mu \mathrm{l}$ ) (Appendix 1 to 7), and the DNA visualised electrophoresis on $1.6 \%$ agarose gel at 100 W for 35 minutes, and viewed under ultraviolet light (uv) (Appendix 10). The DNA was stored in freezer $\left(-20^{\circ} \mathrm{C}\right)$ for PCR amplification later. DNA extraction and PCR amplification for D-loop ananlysis were done at the Biosciences eastern and central Africa-International Livestock Research Institute (BecA-ILRI Hub) laboratories in Nairobi, Kenya. For microsatellite DNA analysis, extracted DNA was freeze-dried and freighted to the University of the Free State in South Africa, where PCR amplification and genotyping was done at the Department of Genetics laboratories.

### 3.4 Primers

Mitochondrial D-loop region primers were used for amplifying the D-loop region. The forward primer was L16473 5'- CTA AAA GCA TCG GTC TTG TAA TCC- $3^{\prime}$ while the reverse primer was H355 5'-CCT GAA ATG AGG AAC CAG ATG- ${ }^{\prime}$ '. Both primers were reconstituted by adding low salt TE buffer to the primers for the
stock solution. To the forward primer, $205 \mu \mathrm{l}$ of buffer was added, to make a stock solution of 100 pmoles $/ \mu \mathrm{l}$. A total of $228.3 \mu \mathrm{l}$ of TE buffer was added to the reverse primer, to make a stock solution of 100 pmoles/ $\mu$ l. From each primer, $10 \mu \mathrm{l}$ was picked and mixed with $90 \mu \mathrm{l}$ of nuclease free water (NFW), to make a working concentration of $10 \mathrm{pmoles} / \mu$ l.

### 3.5 Polymerase Chain Reaction (PCR)

Extracted DNA was PCR amplified in a thermal cycler using a pair of primers (L16473 5' -CTA AAA GCA TCG GTC TTG TAA TCC-3' and H355 5'- CCT GAA ATG AGG AGG AAC CAG ATG- $3^{\prime}$ as the forward and reverse primers respectively) for D-loop gene as used by Nazia et al., (2010). The reaction volume was $20 \mu \mathrm{l}$, containing bioneer premixes, and $18 \mu \mathrm{l}$ distilled water, $0.5 \mu \mathrm{l}$ forward primer and $0.5 \mu 1$ reverse primer, and $1 \mu 1$ of template (sample) DNA normalized to 50 $\mathrm{ng} / \mu \mathrm{l}$, i.e. $1 \mu \mathrm{l}$ of sample to contain 50 ng DNA. This was run in a thermal cycler under the following PCR conditions (Nazia et al., 2010): 5 minutes of initial denaturation at $94^{\circ} \mathrm{C}$, and 35 cycles each of 30 seconds at temperature of $94^{\circ} \mathrm{C}, 30$ seconds at annealing temperature of $56^{\circ} \mathrm{C}, 1$ minute at $72^{\circ} \mathrm{C}$, and a final elongation of 10 minutes at $72^{\circ} \mathrm{C}$. PCR products were electrophoresed on $1.6 \%$ agarose gel stained with $2.5 \mu \mathrm{l}$ of gelRed, and $3 \mu \mathrm{l}$ of each sample of PCR product was loaded into wells, at 100 W for 35 minutes, and visualized under ultraviolet (UV) light.

### 3.6 Purification of PCR products for sequencing

PCR products were purified using the sodium acetate-alcohol precipitation method, as described by Uthice \& Benzie (2003), which involved pelletization of DNA under low temperatures, which is washed off impurities and recovered in distilled water. To a sample of PCR products ( $16 \mu \mathrm{l}$ ) were added $1 / 10$ volumes of 3 molar sodium acetate
of pH 4.8 , and 2.5 volumes of absolute alcohol (iced). A master-mix of the two was prepared to cover all samples of PCR products. The mixture was spinned (Eppendorf centrifuge 5424 R ) for 20 minutes at $14,000 \mathrm{rpm}$ at $4^{\circ} \mathrm{C}$, to pelletize the DNA. The supernatant was discarded and pellet washed with $300 \mu \mathrm{l}$ of $70 \%$ ethanol.

The mixture was spinned (Eppendorf centrifuge 5424R) for 15 minutes at $14,000 \mathrm{rpm}$ at $4^{\circ} \mathrm{C}$. The supernatant was discarded, and the pelletised DNA dried briefly on paper towels, and transferred to a hood (Aura 550E, Labcaire) for 20 minutes for complete drying. The DNA was re-suspended in $20 \mu \mathrm{l}$ distilled water. The purified products were stored at $-20^{\circ} \mathrm{C}$ for use later (sequencing). However, the quality (purity) and quantity of the products and therefore the success of the purification process was confirmed by taking nanodrop readings (on Nanodrop spectrophotometer 2000) and running samples on $1.6 \%$ agarose gel electrophoresis. Before loading the DNA in wells in the agarose gel, $3 \mu$ l DNA was mixed with $3 \mu \mathrm{l}$ orange loading dye in a dilution plate, and all mixture ( $6 \mu \mathrm{l}$ ) loaded in respective wells. The first well on the gel was loaded with $6 \mu$ of 1 kilo-base ( kb ) ladder to help in determining the size of the PCR product. The samples were electrophoresed at 100 w for 35 minutes, before visualization under UV light (Appendix 11).

### 3.7 Sequencing

Purified amplicons of the D-loop region were sequenced with the D-loop reverse primer H 355 on an ABI 3730xl Automated sequencer. The BigDye terminator premix sequencing kit (cat. No. 4336911) was used for sequencing reactions, following the manufacturer's protocol. Products of sequence reaction were cleaned by precipitation in absolute alcohol, re-suspended in $\mathrm{Hi} \mathrm{Di}^{\mathrm{TM}}$ Formamide, before running on the sequencer of 50 cm capillary length.

### 3.8. Microsatellite DNA analysis protocol

Extracted DNA samples of C. gariepinus from 8 sites were tested using 6 SSR markers (Table 3.2), of which 4 (Cga1, Cga3, Cga9 and Cga10) were developed by Galbusera et al., (1996), and 2 (Cba2, Cba19) were developed by Yue et al., (2003). For 4 markers (Cga1, Cga9, Cga10 and Cba2), PCR reaction was carried out in $25 \mu \mathrm{l}$ reaction volume, comprising of $1.25 \mu \mathrm{l}$ each of forward and reverse primers, $8 \mu \mathrm{l}$ of distilled water, $12.5 \mu \mathrm{l}$ of 2 x Kapa2G ${ }^{\text {TM }}$ Robust HotStart Ready mix, and $2 \mu \mathrm{l}$ of template DNA sample.

Table 3.2: Microsatellite DNA primers with nucleotides, range of allele size, dye colour and reference for the 6 loci used to genotype samples of Clarias gariepinus from 8 sites in Kenya.

| Primer | Nucleotides | Size range | Dye colour | Reference |
| :---: | :---: | :---: | :---: | :---: |
| CGA01 | ```5' GGC TAA AAG AAC CCT GTC TG 3' 3' TAC AGC GTC GAT AAG CCA GG 5'``` | 92-104 | Green | Galbusera et al., 1996 |
| CGA03 | ```5' CAC TTC TTA CAT TTG TGC CC 3' 3' ACC TGT ATT GAT TTC TTG CC 5'``` | 142-168 | Blue | Galbusera et al., 1996 |
| CGA09 | ```5' CGT CCA CTT CCC CTA GAG CG 3' 3' CCA GCT GCA TTA CCA TAC ATG 5'``` | 180-196 | Green | Galbusera <br> et al., 1996 |
| CGA10 | $5^{\prime}$ GCT GTA GCA AAA ATG CAG <br> ATG C 3' <br> $3^{\prime}$ TCT CCA GAG ATC TAG GCT <br> GTC C $5^{\prime}$ | 102-138 | Green | Galbusera et al., 1996 |
| CBA02 | $5^{\prime}$ GCC CTG CGA ACA TCT CCA $3^{\prime}$ <br> $3^{\prime}$ TGG CTC CAG CAC TCA CAA $5^{\prime}$ | 176-190 | Yellow | $\begin{aligned} & \text { Yue et al., } \\ & 2003 \end{aligned}$ |
| CBA19 | $\begin{aligned} & \text { 5' CAG GGC TAA ATT ACC CAT } \\ & \text { AAT CA 3' } \\ & \text { 3' }^{\prime} \text { GGC ATG TGT TAT AAC ATG } \\ & \text { TGA GG 5' } \end{aligned}$ | 215-255 | Green | $\begin{aligned} & \text { Yue et al., } \\ & 2003 \end{aligned}$ |

For Cga3, the PCR reaction mix were the same as for above, except $6 \mu 1$ water and 2 $\mu \mathrm{l} \mathrm{mgcl} 2_{2}$ were used, while for Cba19, $7 \mu \mathrm{l}$ water and $1 \mu \mathrm{l} \mathrm{mgcl}{ }_{2}$ were used. The thermal profile for PCR reaction for Cga1, 3, 9 and 10 was: initial denaturation of 3 minutes at $95^{\circ} \mathrm{C}, 35$ cycles of amplification each at $95^{\circ} \mathrm{C}$ for 15 seconds, 15 seconds at respective annealing temperature for each primer, and 15 seconds at $72^{\circ} \mathrm{C}$, with a final elongation step of 10 minutes at $72^{\circ} \mathrm{C}$ and with $15^{\circ} \mathrm{C}$ hold.

For Cba2 and 19, thermal profile for PCR was initial denaturation of 3 minutes at $94^{\circ} \mathrm{C}, 35$ cycles of amplification of 30 seconds at $94^{\circ} \mathrm{C}, 30$ seconds at $56^{\circ} \mathrm{C}$ and 1 minute at $72^{\circ} \mathrm{C}$, with final elongation step of 5 minutes at $72^{\circ} \mathrm{C}$ and with a $15^{\circ} \mathrm{C}$ hold.

Samples were co-loaded with primer sets based on the annealing temperatures of the markers and PCR conditions, i. e.

Load $1 \mathrm{Cga0} 3+$ Cga10: marker sets had annealing temperature of $60^{\circ} \mathrm{C}$, and similar PCR thermal profiles.

Load $2 \mathrm{Cba} 02+\mathrm{Cba} 19:$ marker sets had annealing temperature of $56^{\circ} \mathrm{C}$ and their cycle parameters were the same.

Load 3 Cga01 and Cga09: since each marker had different annealing temperatures, they were loaded separately. Success of PCR was confirmed by electrophoresis on $2 \%$ agarose gel at 100 W for 35 minutes. $1 \mu \mathrm{l}$ of diluted PCR product was added to 8.75 $\mu 1$ of Hi-Di Formamide and $0.25 \mu \mathrm{l}$ of GeneScan-350 ROX size standard and genotyped on the genetic analyzer ABI 3130.

### 3.9. Determination of life-history parameters in populations of Clarias gariepinus from Lakes Victoria, Baringo and Kanyaboli of Kenya.

### 3.9.1. Fecundity

The study focused on three populations of C. gariepinus: Lakes Victoria (LVG), Baringo (LBA) and Kanyaboli (LKG). LVG and LKG represented populations of higher genetic variation, while LBA represented a population of lower genetic variation (Barasa et al., 2017), and following microsatellite DNA analysis in section 4.1.2 and Table 4.2 in the current study. Fish samples were collected monthly for 5 months, from September 2016 to January 2017, from beaches of the three lakes (Appendices 12 to 26). A total of 499, 527 and 354 fish were sampled from Lakes Victoria, Baringo and Kanyaboli respectively. For LVG samples, fish sizes ranged 21 cm and 51.8 g to 107 cm and $3,762 \mathrm{~g}$ (Appendices 12 to 16 ). Fish samples from LBA ranged in size from 29 cm and 136 g to 100 cm and $7,865 \mathrm{~g}$ (Appenndices 17 to 21 ), while for LKG sampled fish ranged in size from 21 cm and 39 g to a length of 82 cm and weight of $3,780 \mathrm{~g}$ (Appendices 22 to 26). For each fish sample, total length was taken (to the nearest 0.1 cm ) on a measuring board, and total weight taken (to the nearest 0.1 g ) on a top loading digital weighing balance (maximum weight 6 kg ). The fish was then dissected, the sex recorded after observing the gonads, and gonads removed carefully and weighed on a top loading digital balance for small weights (maximum $600 \mathrm{~g} * 0.1$ ). The gonad maturity stage of the fish was recorded after careful visual observation of the gonads, and following Bagenal, (1978) and Lung'ayia, (1989). The maturation scheme was as follows: I- immature, II- immature, IIImaturing, IV- mature, V- active, and VI- spent (Table 2.3).

For female fish with eggs (running ripe or maturity stage 5) in the ovary, the removed ovaries (both lobes of ovaries for each fish sample) were placed in small labelled
polythene bags and dissolved in Simpson's solution for estimation of fecundity in the laboratory.

In the laboratory, each of the preserved ovaries was analyzed for fecundity. The sac of the ovary containing the eggs was removed carefully, and the mass of the eggs (both ovaries for each fish sample) weighed again on a digital balance (to the nearest 0.01 g ). Fecundity was determined using the gravimetric method (Bagenal, 1978). The number of eggs making up 1 g for each ovary was counted and recorded. Two more repeats were made on batches of eggs making up 1 g for the same sample of ripe ovary, in order to make three replicates, and an average of the three determined, to get an accurate estimate of the total number of eggs making up 1 g . The total number of eggs in the ovaries for each fish sample was calculated by multiplying the average number of eggs making up 1 g by the total weight of the eggs in both ovaries (Appendices 12 to 26). Relative fecundity of each fish sample was then computed by dividing the total number of eggs by the weight of each female fish from which the eggs were obtained.

### 3.9.2. Size at first maturity

Size at first maturity for the fish samples was determined according to King, (1995) and recently used by Locham et al., (2014). The proportion of mature fish individuals (fish with gonad maturity stages III-V) (Appendices 27 to 32 ) was determined for each length class, and the results fitted to a logistic function using least squares regression in Microsoft Excel.

### 3.9.3. Water quality parameters

During the monthly sampling for fish at each of the three Lakes, water samples were also collected, for analysis of nutrients (total nitrogen and total phosphorus). All water samples were fixed in situ with sulphuric acid, and transported to the laboratory for analysis. Physico-chemical parameters (dissolved oxygen, temperature, specific conductivity, Ph and salinity) were taken at each site using a hydro-lab probe. Total phosphorus was analyzed by the ascorbic acid-molybdate method, while the Kjeldahl method was used to analyze for total nitrogen of the water samples.

### 3.10. Data analyses

### 3.10.1. Mitochondrial (mtDNA) DNA analysis

Raw sequences were aligned, assembled and trimmed in the CLC Bio Main work bench software. This gave a uniform length for the sequences with base pairs of 346 . Duplicate haplotypes were identified using DNAsP (Librado \& Rosas, 2009). Genetic diversity within populations was determined as number of distinct haplotypes, haplotype frequencies and nucleotide diversities, using DNAsP and Arlequin (Excoffier et al., 2005). Arlequin was also used to determine genetic differentiation between populations, expressed as $F_{\text {ST }}$ (Wright, 1965). A maximum likelihood tree was drawn using MEGA (Tamura, 2007), with 1,000 bootstrap repeats, and Clarias liocephalus as the out-group. A minimum spanning Network resolving the relationships between the D-loop haplotypes was drawn using Network 4.56, with a median joining approach (Bandelt et al., 1999), available at http://www.fluxusengineering.com.

### 3.10.2. Microsatellite DNA data analysis

Microsatellite DNA data was scored on Gene mapper, and allele frequencies per population (LVG, LKG, LTA, LBA, SAN, SAG, UoE and KIB), allele counts per population and the size of alleles recorded as per Barasa et al., (2017). The mean observed heterozygosity $\left(H_{O}\right)$ and expected heterozygosity $\left(H_{E}\right)$ values for each population were determined in Microsatellite Toolkit (Park 2001), while the mean number of private alleles were computed in Arlequin version 3.5 (Excoffier et al., 2005).

Departures from Hardy-Weinberg equilibrium (HWE) were tested using Arlequin 3.5 based on permutation method (1,000 iterations) to estimate levels of $F_{\text {IS }}$ values. Similarly, linkage disequilibrium was tested using a randomization test (a permutation method with 1,000 iterations), in Arlequin, and levels of significance tested by the Chi square method. Analysis of molecular variance (AMOVA) (Excoffier et al., 1992) was determined in GenAlEx 6.502 (Peakall \& Smouse, 2012). Using AMOVA, the total variance was partitioned into covariance components attributed to within individuals, among individual and among population differences, with fixation indices computed as $\mathrm{F}_{\mathrm{CT}}$, $\mathrm{F}_{\mathrm{SC}}$ and $\mathrm{F}_{\text {ST }}$ respectively (Wright, 1965). Similarly, the neighbor joining tree showing the phylogenetic relationship of the alleles of the C. gariepinus samples from 8 different sites was generated in GenAlEx 6.502 (Peakall \& Smouse, 2012).

To estimate the number of populations of C. gariepinus present in the microsatellite dataset, the program STRUCTURE 2.3.4 (Pritchard et al., 2000; Falush et al., 2007) was used. STRUCTURE uses a model-based full Bayesian, Markov Chain Monte Carlo (MCMC) approach to assign individuals or samples to the most likely clusters
based on the frequencies of alleles of samples, to minimize Hardy Weinberg disequilibrium and gametic phase disequilibrium between loci within groups. Simulations were on putative populations of K from 2 to 7 . For each K , the posterior probability was calculated using a model-based assignment. Burn-in was set at 10,000 steps, followed by 100,000 MCMC iterations. Simulations were run ten times for each K to check for convergence of the MCMC. Clustering was performed under the admixture model without prior population information, and with correlated allele frequencies between populations. To determine the most likely number of clusters fitting the dataset, the rate of change in the log probability of data between successive K values was evaluated in Structureharvester (Earl \& vonHoldt, 2012), a Python program with a web-based front-end for quickly parsing and summarizing output data from Structure, available at http://taylor0.biology.ucla.edu/structureHarvester.

This was combined with a series of runs of STRUCTURE to identify all the clusters constituting the samples. Membership coefficient of each of the 8 pre-defined populations in each of the identified genetic clusters was determined as an average of outputs of ancestry proportions generated by STRUCTURE 2.3.4, as determined in Barasa et al., (2017).

To determine genetic differentiation between populations of C. gariepinus, Arlequin 3.5 (Excoffier et al., 2005) was used to calculate pair-wise estimates of $F_{\text {ST. }}$. The Fixation index F , is a widely used measure of genetic differentiation between populations (Wright, 1978), and has a minimum of 0 for no genetic differentiation, and a maximum of 1 for a fixation of alternative alleles in the sub-populations.

### 3.10.3. Analysis of data on fecundity and size at first maturity

Mean values of monthly and overall fecundity, and condition factor were computed in Excel, and analysis of variance across populations computed in MINITAB. Size at first maturity $\left(\mathrm{L}_{\mathrm{m} 50}\right)$ was determined from a logistic curve equations:

$$
\operatorname{Ln}(1(1 / \mathrm{P} 1)-1=\mathrm{S} 1-\mathrm{S} 2 * \mathrm{~L}
$$

$$
\mathrm{L}_{\mathrm{M} 50}=\mathrm{S} 1 / \mathrm{S} 2,
$$

Where PL is the probability of maturity at length $\mathrm{L}, \mathrm{S} 1$ is the intercept, and S 2 the slope.

## CHAPTER FOUR

## RESULTS

### 4.1. Genetic diversity of Clarias gariepinus inferred from mitochondrial D-loop control region and microsatellite DNA markers.

### 4.1.1. Mitochondrial D-loop control region

The nucleotide diversity $(\pi)$ for the lake (natural) samples ranged from a low of 0.006 in Lake Kanyaboli (LKG) to a high of 0.037 in Lake Jipe (LJP) (Table 4.1). In samples from fish farms, nucleotide diversity was low in both Sangoro (SAN) and Wakhungu Fish Farm (WKU), at 0.006, but higher in Sagana (SAG) which had a value of 0.067 . However, nucleotide diversity for University of Eldoret Fish Farm (UoE) and Kibos Fish Farm (KIB) samples was intermediate at 0.009 . The number of haplotypes was $13,10,8,8,12,9,14,7,7$ and 9 for LVG, LKG, LTA, LBA, LJP, SAN, SAG, WKU, UoE, and KIB populations respectively (Table 4.1). The number of haplotypes was generally higher in natural than farmed samples, except for SAG, which recorded the highest number of haplotypes among samples from the 10 sites.

All samples from the 10 sites except LTA and LJP shared haplotypes (Table 4.1). A total of 8 haplotypes were shared among the samples. This therefore left each of the populations with a number of singletons (private haplotypes), with LJP having the highest at 12 (haplotypes $\mathrm{H}-18$ to 29) (Appendix 8) followed by SAG with 10 (haplotypes H-51 to 60). LTA had 8 (haplotypes H-36 to 43), while LVG and LBA had 7 private haplotypes each ( $\mathrm{H}-44$ to 50 and $\mathrm{H}-10$ to 13 , 15 to 17 respectively). LKG had 5 (haplotypes H-30 to 32, 34 to 35) while SAN had 4 (H-61 to 64). UoE had 3 (H-65 to 67), while KIB and WKU had a single private haplotype each (H-7 and H-

68 respectively). Therefore, with the exception of SAG, all samples from fish farms had a lower number of singletons than samples from natural sites (Table 4.1).

Similarly, a total of 386 segregating sites defined 68 haplotypes from the 268 samples (sequences), and $88.2 \%$ of the haplotypes were private.

Table 4.1. Genetic diversity values for samples of Clarias gariepinus from $\mathbf{1 0}$ different sites in Kenya inferred from mtDNA D-loop region. $\Pi$ is the nucleotide diversity and $\boldsymbol{h}$ is the haplotype diversity.

| Population | LVG | LKG | LTA | LBA | LJP | SAN | SAG | WKU | UoE | KIB |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Sample | 25 | 26 | 28 | 24 | 32 | 30 | 23 | 25 | 29 | 26 |
| $\Pi$ | 0.009 | 0.006 | 0.009 | 0.006 | 0.037 | 0.006 | 0.067 | 0.006 | 0.009 | 0.009 |
| No of <br> haplotypes | 13 | 10 | 8 | 8 | 12 | 10 | 14 | 7 | 7 | 9 |

Therefore, 8 of the haplotypes were shared among the populations. Haplotype 2 was the most frequent (Appendix 8), appearing in 76 individuals of the LVG group.

The diversity of haplotyes was consistent with the number of haplotypes, where populations with a higher number of haplotypes also had a higher diversity of haplotypes. However, LJP which had the third highest number of haplotypes had the lowest haplotype diversity (Table 4.1). Haplotype diversity values ranged from 0.6794 in LJP to 0.9407 in SAG, with most of the farmed samples showing lower
values than samples from natural sites (Table 4.1). The D-loop region in the samples of C. gariepinus segregated at a total of 386 polymorphic sites, with LJP having the highest with 161sites, while SAG had 112, LVG and LKG had 21 and 18 sites respectively. LBA had 16, SAN, UoE and LTA 12 sites each, while WKU and KIB had 11 each.

### 4.1.2. Genetic diversity of samples of Clarias gariepinus from 8 sites in Kenya inferred from microsatellite DNA markers genotyped at 6 loci.

The mean number of alleles per locus ( Na ) was generally higher in farmed than natural C. gariepinus populations (Table 4.2). SAN had the highest mean number of alleles per locus ( $10.83 \pm 3.66$ ), while LBA had the lowest mean number of alleles ( $3.80 \pm 0.84$ ). Among the natural populations, LKG had a relatively higher number of alleles ( $8.17 \pm 3.31$ ), while LVG and LTA had an equal number of alleles ( $8.00 \pm 3.52$ ). All the farmed populations except SAG had higher mean number of alleles per locus than natural populations. The mean observed heterozygosity $\left(H_{\mathrm{O}}\right)$ was moderate in populations, ranging from $0.47 \pm 0.05$ in LBA to $0.80 \pm 0.04$ in SAN. $H_{\mathrm{O}}$ values for LVG, LKG, LTA, SAG, UoE and KIB were $0.79 \pm 0.05,0.72 \pm 0.05,0.74 \pm 0.05,0.55$ $\pm 0.05, \quad 0.74 \pm 0.04$, and $0.70 \pm 0.05$ respectively. Similarly values for expected heterozygosities $\left(H_{\mathrm{E}}\right)$, ranged from $0.58 \pm 0.05$ in LBA to $0.84 \pm 0.05$ in LVG, and were slightly higher than $H_{\mathrm{O}}$ values. $H_{E}$ values for LKG, LTA, SAN, SAG, UoE and KIB were $0.83 \pm 0.05, \quad 0.82 \pm 0.04, \quad 0.84 \pm 0.04, \quad 0.76 \pm 0.04, \quad 0.82 \pm 0.04$ and $0.85 \pm 0.04$ respectively (Table 4.2).

All the populations had private alleles, with KIB reporting the highest mean number at $5.91 \pm 0.67$, LVG with $5.86 \pm 0.79$, LBA with $5.75 \pm 0.43$, while UoE had $5.61 \pm 0.56$.

SAG, LTA and SAN had $5.55 \pm 0.62,5.53 \pm 1.11$ and $5.50 \pm 0.78$ mean number of private alleles respectively.

Table 4.2: Level of genetic diversity in 160 samples of Clarias gariepinus from 8 different sites in Kenya, genotyped with 6 microsatellite DNA loci.N is the sample size at each sampling site, Na is the number of alleles, $H_{O}$ is the observed heterozygsity, $H_{E}$ is the expected heterozygosity, while $F_{\text {IS }}$ is the coefficient of inbreeding. $\mathbf{F}_{\text {IS }}$ values in bold are significantly different at $\mathbf{p}<\mathbf{0 . 0 5}$. Values are given as mean $\pm$ standard error (S.E).

| Population | $\mathbf{N}$ | $\mathbf{N a}$ | $\boldsymbol{H}_{\mathbf{O}}$ | $\boldsymbol{H}_{\mathbf{E}}$ | No. of <br> private <br> alleles | Coefficient <br> of <br> inbreeding <br> $\left(\boldsymbol{F}_{\text {IS }}\right)$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| LVG | 23 | $8.00 \pm 3.52$ | $0.79 \pm 0.05$ | $0.84 \pm 0.05$ | $5.86 \pm 0.79$ | -0.614 |
| LKG | 20 | $8.17 \pm 3.31$ | $0.72 \pm 0.05$ | $0.83 \pm 0.05$ | $5.47 \pm 0.87$ | $\mathbf{0 . 1 1 2}$ |
| LTA | 19 | $8.00 \pm 2.68$ | $0.74 \pm 0.05$ | $0.82 \pm 0.04$ | $5.53 \pm 1.11$ | 0.266 |

| SAN | 20 | $10.83 \pm 3.66$ | $0.80 \pm 0.04$ | $0.84 \pm 0.04$ | $5.50 \pm 0.78$ | 0.016 |
| SAG | 20 | $7.67 \pm 2.73$ | $0.55 \pm 0.05$ | $0.76 \pm 0.04$ | $5.55 \pm 0.62$ | $\mathbf{0 . 2 5 0}$ |
| UoE | 20 | $8.83 \pm 2.56$ | $0.74 \pm 0.04$ | $0.82 \pm 0.04$ | $5.61 \pm 0.56$ | $\mathbf{0 . 0 9 5}$ |
| KIB | 20 | $9.67 \pm 2.88$ | $0.70 \pm 0.05$ | $0.85 \pm 0.04$ | $5.91 \pm 0.67$ | $\mathbf{0 . 0 6 9}$ |

On the other hand, out of the 8 sites from which C. gariepinus was sampled, 4 had significantly different ( $\mathrm{p}<0.05$ ) coefficients of inbreeding $\left(F_{I S}\right)$, indicating that the fish were inbred. The inbred samples were LKG, SAG, UoE and KIB, with $F_{I S}$ values ranging from 0.069 to 0.250 . $F_{I S}$ values for LVG, LTA, LBA, and SAN ranged from 0.016 to 0.266 , and were not significantly different ( $\mathrm{p}>0.05$ ).

Table 4.3: P-values for Hardy Weiberg Equilibrium (HWE) Exact tests for 160 samples of C. gariepinus sampled from 8 different sites (4 natural and 4 fish farms) in Kenya. Samples were genotyped with 6 loci. Values in bold are significantly different at $\mathbf{p}<0.01$, and $\mathbf{p}<0.05$.

| Population | Locus <br> Cga1 | Cga3 | Cga9 | Cga10 | Cba2 | Cba19 |

4.2. Population genetic structure of Clarias gariepinus in Kenya inferred from mtDNA D-loop control region.
4.2.1. Population differentiation indices $\left(F_{\mathrm{ST}}\right)$ of samples of Clarias gariepinus from 10 different sites in Kenya.

There was population differentiation among the 10 populations, with significantly different ( $\mathrm{p}<0.05$ ) population differentiation $\left(F_{\mathrm{ST}}\right)$ indices among 31 out of 45 pair wise comparisons, mainly for LTA, LBA, and LJP with other populations, and LVG compared with samples from the natural populations (Table 4.4). Pair-wise population comparisons without differentiation (i.e. with $F_{\text {ST }}$ values not significantly different ( $\mathrm{P}>0.05$ )) included comparisons of LVG or LKG with samples from farms, and comparisons among farmed samples. $F_{\mathrm{ST}}$ values ranged from 0.00007 for LKG-SAN to 0.9620 for LJP-SAG comparisons (Table 4.4).

Table 4.2: Pair wise comparisons of $\mathbf{F}_{S T}$ values of samples of Clarias gariepinus from 10 different sites in Kenya inferred from sequences of mtDNA D-loop control region. Values in bold are significantly different ( $\mathbf{P}<\mathbf{0 . 0 5}$ ). A total of 31 of 45 pair wise comparisons are significantly different. 1 is LVG, 2 is LKG, 3 is LTA, 4 is LBA, 5 is LJP, 6 is SAN, 7 is SAG, 8 is WKU, 9 is UoE and 10 is KIB.

4.2.2. Maximum likelihood tree for phylogenetic relationships among samples of Clarias gariepinus from 10 sites in Kenya.

From the Maximum likelihood tree (Figure 4.1), haplotypes of C. gariepinus samples grouped into 5 clusters: cluster 1 comprised of the LVG population, which, apart from LVG haplotypes, also included haplotypes from LKG, SAN, KIB, UoE and SAG. The second cluster comprised haplotypes of LJP population, which did not have any shared haplotypes. Cluster 3 comprised LBA and included samples from two farms
(UoE and WKU). Cluster 4 comprised of LTA haplotypes, and included haplotypes from SAG, while the last cluster was SAG which also carried haplotypes from SAN.

Figure 4.1: Maximum likelihood tree illustrating the clustering of haplotypes for samples of Clarias gariepinus from 10 different sites in Kenya inferred from sequences of mtDNA D-loop control region. Haplotypes of the samples grouped into 5 clusters. Numbers on branches are percentage bootstrap values based on 1,000 replicates, and nodes without numbers have confidence levels less than $\mathbf{5 0 \%}$. Clarias liocephalus is the out-group. Source: Author, 2014.

### 4.2.3. Minimum spanning networks for phylogenetic relationships among samples of Clarias gariepinus from 10 different sites in Kenya.

The haplotype network for C. gariepinus samples showed 5 distinct clusters (Figure 4.2), consistent with the Maximum likelihood tree: the LVG, LBA, LTA LJP and SAG. Cluster 1, the LVG group, comprised LVG haplotypes and haplotypes from LKG and all the farmed populations, while cluster 2 comprised mainly of LBA, with haplotypes of UoE, SAN and SAG. Although some haplotypes of LVG were present in cluster 2, LBA haplotypes were virtually absent in cluster 1 . Cluster 3 comprised LTA haplotypes, and did not have any shared haplotype. Cluster 4 had haplotypes of SAG. Similarly, LJP which formed the fifth cluster was distinct from the other clusters, sharing haplotypes with no other populations. Haplotype 2 was the most common, appearing in a total of 76 samples (Appendix 8). Therefore, haplotype 2 could be the ancestral haplotype, from which all the other samples radiated via 1 to 8 mutation steps.

Figure 4.2: Haplotype networks for samples of Clarias gariepinus from 10 different sites in Kenya, inferred from sequences of mtDNA D-loop control region. A total of 5 clusters comprising LVG (cluster 1), LBA (cluster 2), LTA (cluster 3), SAG (cluster 4) and LJP (cluster 5) are discerned. Source: Author, 2014.

### 4.3. Population genetic structure of samples of Clarias gariepinus from 8 sites in Kenya inferred from microsatellite DNA markers.

### 4.3.1. Analysis of molecular variance (AMOVA) of samples of C. gariepinus.

The analysis of molecular variance revealed that sub-divisions among populations contributed the lowest to the total observed variation in the samples of C. gariepinus, with only $22 \%$ variance (Table 4.5). However, the sub-division among populations contributed significantly $\left(\mathrm{F}_{\mathrm{ST}}=0.221, \mathrm{p}<0.05\right)$ to the genetic structure of the samples. On the other hand, the sub-division among individuals contributed slightly higher to the observed variation with $26 \%$, and this contribution to the genetic structure of the samples was also significant $\left(\mathrm{F}_{S C}=0.333, \mathrm{p}<0.05\right)$. The sub-division within
individuals contributed the highest (52\%) to observed variation in samples of $C$. gariepinus, with a significantly higher ( $\mathrm{F}_{\mathrm{CT}}=0.481, \mathrm{p}<0.05$ ) contribution to the genetic structure of the samples.

Table 4.3: Analysis of molecular variance among alleles of C. gariepinus samples from 8 different sites of Kenya.

| Source | d.f | Sum of squares | Variance components | Percentage of variation | Fixation index | $\begin{aligned} & \text { p- } \\ & \text { value } \end{aligned}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| Within individuals | 80 | 107.000 | 1.338 | 52 | $\begin{aligned} & \mathrm{F}_{\mathrm{CT}}= \\ & 0.481 \end{aligned}$ | 0.001 |
| Total | 159 | 386.338 | 2.575 | 100 |  |  |

### 4.3.2. Neighbor joining tree for phylogenetic relationships among samples of $\boldsymbol{C}$. gariepinus.

A total of four genetic clusters were deciphered from alleles of $C$. gariepinus samples from 8 sites in Kenya. These were the Lake Victoria (LVG), Lake Turkana (LTA), Lake Baringo (LBA) and SAG (Sagana Aquaculture center) clusters. The clusters grouped interchangeably in the neighbor joining tree (Fig. 4.3). Farmed samples grouped predominantly in the LVG cluster, although some farmed samples also grouped in the SAG and LTA clusters. Samples of LKG also grouped in the LVG cluster.

Figure 4.3: Neighbor joining tree of alleles of C. gariepinus samples from 8 different sites in Kenya, genotyped at 6 microsatellite loci. 4 genetic clusters are discerned, in which alleles of C. gariepinus samples grouped: LVG (Lake Victoria), LBA (Lake Baringo), LTA (Lake Turkana), and SAG (Sagana Aquaculture center). Source: Author, 2017.
4.3.3. Population genetic structure of samples of C. gariepinus using STRUCTURE.

Samples were arranged according to the sampling site: LVG, LKG, LTA, LBA, SAN, SAG, UoE and KIB. All samples from the four fish farms (SAN, SAG, UoE and KIB) and LKG from the wild, grouped with LVG. UoE, KIB and SAN also grouped with LBA (Figure 4.4). Four distinct genetic clusters were discerned, identified as LVG, LTA, LBA and SAG.

Figure 4.4: Bar plot of the STRUCTURE assignment test for 160 samples of Clarias gariepinus collected from 8 different sites (4 lakes- LVG, LKG, LTA and LBA, and 4 farms-SAN, SAG, UoE and KIB) in Kenya, and genotyped with 6 microsatellite DNA loci. Source: Author, 2016.

Samples from the LVG and LKG pre-defined population dominated the LVG cluster, with a membership coefficient of 0.4483 and 0.7592 respectively. Similarly, the LBA, LTA and SAG clusters were dominated by samples from the LBA, LTA and SAG pre-defined populations respectively, as evidenced by high respective membership coefficients (Table 4.6).

Table 4.4: Proportion of membership of each pre-defined population in each of the 4 genetic clusters $(K=4)$ inferred in samples of Clarias gariepinus from 8 different sites in Kenya genotyped at 6 microsatellite DNA loci. STRUCTURE was run with $\mathbf{1 0 , 0 0 0}$ Burn-in period and $\mathbf{1 0 0 , 0 0 0}$ Monte Carlo simulations.

| Pre-defined <br> Population | Inferred genetic cluster | Sample <br> size |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | LVG/LKG | LBA | SAG | LTA |  |
| LVG | 0.4482 | 0.0400 | 0.0690 | 0.4429 | 23 |
| LKG | 0.7592 | 0.0094 | 0.0538 | 0.1776 | 20 |
| LTA | 0.0733 | 0.0561 | 0.0466 | 0.8241 | 19 |
| LBA | 0.0099 | 0.9748 | 0.0052 | 0.0101 | 18 |
| SAN | 0.5385 | 0.0119 | 0.0239 | 0.4257 | 20 |
| SAG | 0.2339 | 0.0380 | 0.6219 | 0.1062 | 20 |
| UoE | 0.5873 | 0.0131 | 0.0131 | 0.3865 | 20 |
| KIB | 0.7092 | 0.0110 | 0.0138 | 0.2660 | 20 |

The number of genetic clusters (the actual populations) in the samples from the 8 sites was $4(\mathrm{~K}=4)$, i.e. the number corresponding to the highest peak in the output of the STRUCTUREHARVESTER (Figure 4.5). In the web based program, the most likely number of K that best suits the dataset is inferred at the point where the rate of change in the $\log$ of likelihood of prior probability of K ceases to increase, or plateaus off (Earl and vonHoldt, 2012).

From biological information, the first three clusters were identified as LVG, LTA and LBA.

Figure 4.5: The most likely number of populations $\mathbf{K}$ for the samples of Clarias gariepinus, as implemented in the Evanno method. Samples were drawn from the following sites LVG, LKG, LTA, LBA, SAN, SAG, UoE, and KIB. Source: Author, 2014.

DeltaK $=$ mean $(|L ’ ’(K)|) / s d(L(K))$.

The first three of the 4 populations inferred from STRUCTURE are LVG, LTA and LBA (Fig. 4.5). In order to infer the fourth population out of the remaining samples, a series of runs of STRUCTURE were made using samples from 7 sites (i.e. excluding 1 of the five LKG, SAN, SAG, UoE or KIB) during each run (Barasa et al., 2017). For each of the 5 combinations, STRUCTURE HARVESTER analysis returned an output of $\mathrm{K}=3$, except when SAG was included in the run, that K changed to 4 (Figure 4.6).

Figure 4.6: Output of STRUCTUREHARVESTER with 4 as the most likely number of populations $K$, as implemented in the Evanno method. This output was obtained only when SAG (out of the four possible sites of SAN, SAG, UoE, and KIB) was included in the samples included in the run of STRUCTURE. Source: Author, 2014.

### 4.3.4. Population differentiation indices $\left(F_{\mathrm{ST}}\right)$ of populations of Clarias gariepinus

 inferred from Microsatellites DNA analysis.The pattern of population differentiation among samples was similar to that reported in the mtDNA analysis, with significantly different ( $\mathrm{p}<0.05$ ) $F_{\mathrm{ST}}$ values being reported in 15 out of 28 pair-wise comparisons (Table 4.7). The Significantly different values were reported in comparisons of samples from natural populations. However, comparisons of natural and farmed samples revealed significantly different ( $\mathrm{p}<0.05$ ) $F_{\mathrm{ST}}$ values only in comparisons of LTA and farmed samples, and also LBA with farmed samples (Table 4.7).

Table 4.5: Estimates of pairwise $\boldsymbol{F}_{S T}$ values, for 160 samples of Clarias gariepinus collected from 8 sites (LVG, LKG, LTA, LBA, SAN, SAG, UoE and KIB) in Kenya and genotyped at 6 microsatellite loci. Values in bold are significantly different ( $\mathbf{p}<\mathbf{0 . 0 5}$ ). A total of 15 out of 28 pair wise comparisons are significantly different. LJP and WKU were not included in genotyping.

4.4. Life-history parameters and genetic diversity of three populations (Lakes Victoria, Kanyaboli and Baringo) of Clarias gariepinus of Kenya.

### 4.4.1. Relative Fecundity

The mean monthly relative fecundity among the three natural populations of $C$. gariepinus was significantly different ( $\mathrm{p}<0.05$ ) in the months of October ( $\mathrm{F}=5.559$, $\mathrm{p}=0.009$ ) and December ( $\mathrm{F}=8.869, \mathrm{p}=0.0009$ ) 2016, but not significantly different ( $\mathrm{p}>0.05$ ) in the months of September ( $\mathrm{F}=0.177, \mathrm{p}=0.839$ ), November ( $\mathrm{F}=1.707$, $\mathrm{p}=0.196$ ) and January ( $\mathrm{F}=2.862, \mathrm{p}=0.072$ ) (Table 4.8). In both October and December, relative fecundity was significantly higher in LVG than LBA and LKG, but not significantly different ( $\mathrm{p}>0.05$ ) among LBA and LKG. The overall mean relative fecundity was significantly different among the three populations $(\mathrm{F}=9.593$,
$\mathrm{p}=0.0001$ ), with the relative fecundity of LVG being higher than LBA and LKG ( $\mathrm{p}<0.05$ ), but similar among LBA and LKG ( $\mathrm{p}>0.05$ ).

Table 4.6: Mean monthly relative fecundity ( $\pm$ S.E) of LVG, LBA and LKG populations of Clarias gariepinus, with respective p-values, sampled for 5 months from September 2016 to January 2017. Values with similar superscripts in a row are statistically similar.

| Month | LVG | LBA | LKG | ANOVA <br> F | P-value |
| :--- | :--- | :--- | :--- | :--- | :--- |
| September | $62.3 \pm 12.1^{\mathrm{a}}$ | $76.7 \pm 27.9^{\mathrm{a}}$ | $78.8 \pm 13.5^{\mathrm{a}}$ | 0.177 | 0.839 |
| October | $79.1 \pm 6.5^{\mathrm{a}}$ | $42.8 \pm 7.3^{\mathrm{b}}$ | $56.3 \pm 9.8^{\mathrm{b}}$ | 5.559 | 0.009 |
| November | $96.0 \pm 15.4^{\mathrm{a}}$ | $67.3 \pm 9.5^{\mathrm{b}}$ | $65.5 \pm 11.9^{\mathrm{b}}$ | 1.707 | 0.196 |
| December | $95.2 \pm 13.7^{\mathrm{a}}$ | $38.4 \pm 5.2^{\mathrm{b}}$ | $52.3 \pm 11.2^{\mathrm{b}}$ | 8.869 | 0.0009 |
| January | $66.4 \pm 12.6^{\mathrm{a}}$ | $39.9 \pm 6.6^{\mathrm{b}}$ | $33.4 \pm 8.4^{\mathrm{b}}$ | 2.862 | 0.072 |
| Overall means | $81.9 \pm 6.0^{\mathrm{a}}$ | $50.8 \pm 5.6^{\mathrm{b}}$ | $53.0 \pm 5.1^{\mathrm{b}}$ | 9.593 | 0.0001 |

### 4.4.2. Size at first maturity $\left(L_{m 50}\right)$

In the Lake Victoria population, C. gariepinus females reached sexual maturity at a total length of 55.0 cm , while males matured at 57.0 cm total length (Fig. 4.7).

Figure 4.7: Size at first maturity of Clarias gariepinus population of Lake Victoria (LVG). Data is based on 499 fish samples collected over 5 months (September 2016 to January 2017).

In LBA population, females matured at a total length of 57.0 cm , while males matured later at 60.0 cm total length (Fig. 4.8).

Figure 4.8: Size at first maturity of Clarias gariepinus population of Lake Baringo (LBA). Data is based on 527 fish samples collected over 5 months (September 2016 to January 2017).

In LKG, males matured at a total length of 51 cm , while females matured earlier at 48 cm total length (Fig. 4.9).

Figure 4. 9: Size at first maturity of Clarias gariepinus population of Lake Kanyaboli (LKG). Data is based on 354 fish samples collected over 5 months (September 2016 to January 2017). Total length is in cm.

### 4.4.3. Water quality parameters

There was no significant difference ( $\mathrm{p}>0.05$ ) in the overall mean values of nutrients among the three lakes during the study period (Table 4.9). Total phosphorus was similar among the study sites $(\mathrm{F}=1.24, \mathrm{p}=0.218)$, while total nitrogen was also similar among the lakes $(\mathrm{F}=2.4, \mathrm{p}=0.133)$.

Table 4.7: Overall mean values of nutrients (total phosphorus and total nitrogen) of Lakes Victoria, Baringo and Kanyaboli over the study period of September 2016 to January 2017.

|  | Sampling Sites (Populations) |  | Anova |  |  |
| :--- | :--- | :--- | :--- | :---: | :---: |
| Nutrients | LVG | LBA | LKG | F | P |
| Total phosphorus <br> $(\mathrm{mg} / \mathrm{L})$ | $0.085 \pm 0.019$ | $0.054 \pm 0.006$ | $0.079 \pm 0.006$ | 1.74 | 0.218 |
| Total Nitrogen <br> $(\mathrm{mg} / \mathrm{L})$ | $0.902 \pm 0.053$ | $0.65 \pm 0.046$ | $0.826 \pm 0.126$ | 2.4 | 0.133 |

The overall physico-chemical parameters were all significantly different ( $\mathrm{p}<0.05$ ) among the three study sites (Table 4.10). The pH was significantly lower in LVG than LBA and LKG which had similar values. On the other hand, salinity and specific conductivity were significantly higher in LBA than both LVG and LKG, which had similar values, while total dissolved solids was significantly higher in LBA than LVG and LKG. However, LKG had a significantly higher value for TDS than LVG. Water temperature was significantly lower in LVG than LBA and LKG, which had similar values.

Table 4.10: Overall mean values of physico-chemical parameters of Lakes Victoria, Baringo and Kanyaboli over the study period of September 2016 to January 2017. Mean values with different letter superscripts in a row are significantly different as the SNK test.

|  | Sampling Sites (Populations) |  |  |  | ANOVA |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :---: |
| Variable | LVG | LBA | LKG | F | P |  |
| pH | $5.83 \pm 0.07^{\mathrm{a}}$ | $6.49 \pm 0.030^{\mathrm{b}}$ | $6.37 \pm 0.12^{\mathrm{b}}$ | 10.63 | 0.001 |  |
| Salinity | $0.16 \pm 0.04^{\mathrm{a}}$ | $0.42 \pm 0.04^{\mathrm{b}}$ | $0.22 \pm 0.03^{\mathrm{a}}$ | 13.16 | 0.001 |  |
| Specific | $0.21 \pm 0.02^{\mathrm{a}}$ | $0.59 \pm 0.06^{\mathrm{b}}$ | $0.38 \pm 0.06^{\mathrm{a}}$ | 36.56 | 0.001 |  |
| conductivity (SPC) <br> Total Dissolved <br> Solids (TDS) <br> Temperature $\left({ }^{\circ} \mathrm{C}\right)$ <br> $13.6 \pm 0.46^{\mathrm{c}}$ | $66.2 \pm 4.21^{\mathrm{a}}$ | $44.05 \pm 6.26^{\mathrm{b}}$ | 12.28 | 0.001 |  |  |

4.4.4. Association between heterozygosity and relative fecundity of the populations of Clarias gariepinus from Lakes Victoria, Baringo and Kanyaboli.

There was an association between mean expected heterozygosity and mean relative fecundity of C. gariepinus from the three lakes. The Lake Victoria population (LVG), with a higher mean heterozygosity than both LBA and LKG, also reported a higher mean relative fecundity than LBA and LKG. However, although LKG had a higher mean heterozygosity than LBA, had similar mean relative fecundity with the LBA population (Fig. 4.10).

Figure 4.10: Relationship between mean relative fecundity and the expected Heterozygosity $\left(H_{E}\right)$ of Clarias gariepinus populations from Lakes Victoria (LVG), Baringo (LBA) and Kanyaboli (LKG). Source: Author, 2017.

For male samples of C. gariepinus, the size at first maturity was higher in LBA than in LVG and LKG, although LBA had a lower $H_{E}$ than both LVG and LKG populations. However, male C. gariepinus from LVG had a higher size at first maturity than LKG; consistent with the higher $H_{E}$ recorded in LVG than LKG populations (Fig. 4.11).

Figure 4.11: Relationship between mean size at first maturity ( $\mathrm{L}_{\mathrm{m}} 50$ ) and the mean expected Heterozygosity $\left(H_{E}\right)$ of male samples of Clarias gariepinus populations from Lakes Victoria (LVG), Baringo (LBA) and Kanyaboli (LKG). Source: Author, 2017.

The comparison of size at first maturity and $H_{E}$ of female fish from the three populations showed similar pattern as that observed in male fish samples, with LBA recording higher size at first maturity than both LVG and LKG (Fig. 4.12). A higher size at first maturity was also observed in female fish of LVG than LKG, consistent with the higher $H_{E}$ in LVG than LKG.

Figure 4.12: Relationship between mean size at first maturity ( $\mathrm{L}_{\mathrm{m}} 50$ ) and the mean expected Heterozygosity $\left(H_{E}\right)$ of female samples of Clarias gariepinus populations from Lakes Victoria (LVG), Baringo (LBA) and Kanyaboli (LKG). Source: Author, 2017.

## CHAPTER FIVE

## DISCUSSION

### 5.1. Genetic diversity of C. gariepinus inferred from mitochondrial D-loop control region and microsatellite DNA data

The nucleotide diversity of the catfish populations was low, while haplotype diversity was high, reaching almost 1 , with the exception of the SAN, which had low value of 0.087. This shows that genetic variation in the populations could be accounted for by within population variation. However, indices of haplotype and nucleotide diversity were similar to values reported for C. gariepinus populations from South Africa, which ranged from $0.838 \pm 0.030$ to $0.904 \pm 0.019$ and $0.006 \pm 0.003$ to $0.008 \pm 0.040$ respectively (Roodt-Wilding et al., 2010). The presence of shared haplotypes implies there was gene flow among the populations, and this was restricted to farmed populations (UoE, SAG, SAN, WKU and KIB), which were mainly sourced from Lake Victoria, or from other fish farms that initially collected their brood stock from L. Victoria. Translocation of fish populations across drainage basins for aquaculture is common, especially in C. gariepinus aquaculture that frequently depends on collection of males from natural populations to provide the pituitary hormone and milt during artificial propagation at hatcheries. In their study of three populations of $C$. macrocephalus in Malaysia, Nazia et al., (2010) reported that human transfer of brood stock across drainage basins was responsible for homogenizing geographically isolated populations of the species.

Apart from reporting a higher number of haplotypes (Table 4.1), SAG also clustered close to LTA in the haplotype spanning network (Figure 4.2), which showed relatively higher genetic diversity for this population compared to samples from different farms (SAN, UoE, KIB and WKU). A possible reason for higher genetic
diversity in SAG could be mixed gene pools, from fish with multiple sources. Artificial propagation of C. gariepinus at hatcheries necessitates a collection of male brooders from other natural sites such as swamps, rivers and streams to provide pituitary to induce ovulation, and milt for fertilization of eggs. Similarly, when the number of female brooders at the hatchery decreases, more samples are collected from these natural sites, to augment the number of brood stock. These practices therefore have a similar effect on genetic diversity of brood stock as the deliberate introduction of genetically different fish brood stock by hatcheries to boost genetic variability of brooders that have been kept and used on a farm for many generations (Van der Bank et al., 1992; Grobler et al., 1997).

In addition, farmed populations, except the SAG population, reported lower haplotype diversity while natural populations had higher haplotype diversity values. This could be attributed to the effect of domestication, where farmed fish generally lose genetic diversity. Aquaculture practices like intensive selection for superior traits in a breeding program invariably lead to inbreeding (Norris et al., 1999), because in the absence of pedigree records, closely related families are used for breeding, leading to inbreeding depression. Inbreeding, founder effects and genetic drift reportedly erode genetic variability in farmed catfishes (Van Der Walt et al., 1993; Popoola et al., 2014), as well as other aquaculture species such as salmonids (Su et al., 1996; Bourret et al., 2011) and tilapias (Eknath \& Hulata, 2009). Loss of genetic variability potentially affects adaptability, persistence of fish in habitats and productivity of the fish population (Hauser et al., 2002).

Of the 5 natural populations sampled, LKG and LJP had the lowest haplotype diversities. Both lakes are small and isolated (L. Kanyaboli is $10.5 \mathrm{~km}^{2}$, L. Jipe 30 $\mathrm{km}^{2}$, L. Baringo $130 \mathrm{~km}^{2}$, L. Turkana $7,000 \mathrm{~km}^{2}$ while L. Victoria is $69,000 \mathrm{~km}^{2}$ in
surface area), and higher fishing pressure, especially in LKG population (Aloo, 2003), could have reduced its genetic diversity. Higher fishing pressure is known to reduce genetic diversity in fish populations, through fishing mortality (Van Der Walt et al., 1993). Small and isolated populations also suffer lower genetic diversity due to genetic drift that results from founder effects and lower effective population sizes (Nei et al., 1975). Although the haplotype diversity values of LVG, LBA, LTA and LJP were comparable, at $0.910,0.877,0.825$ and 0.6794 respectively, LVG had a slightly higher diversity, which was expected, because of its larger population size, as reported by similar studies (Barasa et al., 2014).

On the other hand, $88.2 \%$ of the haplotypes were private, distributed in each of the ten populations. The presence of private haplotypes reflects high population differentiation, facilitated by geographical separation of the study sites by distance, and small sizes of both the study populations and samples. For instance, LJP which had the highest number of singletons is small and isolated. Apart from its small size, Lake Kanyaboli is isolated, and fringed by dense papyrus, which restricts the exchange of fish with surrounding watermasses (Abila et al., 2004; Barasa et al., 2016). Small populations and sample sizes often suffer genetic drift (Frankharm et al., 2002), and impact genetic differentiation of populations (Barasa et al., 2016), leading to private haplotypes in the populations. These haplotypes need to be conserved by managing the populations separately, and harnessing the haplotypes into aquaculture programs, as reported by Nazia et al., (2010); Roodt-Wilding et al. 2010; Chemoiwa et al., (2013) and Barasa et al., (2014; 2016; 2017).

Generally, higher genetic variation occurs in natural than farmed fish populations. This is reported in the Indian major carp Catla catla (Alam \& Islam, 2005; Hansen et al., 2006), the Turbot Scophthalmus maximus (Coughlan et al., 1998), Atlantic salmon
(Norris et al., 1999) and the Channel catfish, I. punctatus (Perales-Flores et al., 2007). These studies demonstrate the potential impacts of domestication on genetic variability in fish, which occurs by inbreeding that decreases the fitness of populations (Hansen et al., 2006), fixation of deleterious alleles or due to absence of variation at loci showing over-dominance (Hedrick \& Kalinowski, 2000). Allelic variation is necessary for maintaining evolutionary potential, important for selective breeding for commercially important traits in captive populations (Frankham et al., 2002).

However, in this study, all farmed samples except SAG had higher number of alleles than natural populations. This could be attributed to artificial propagation practices at hatcheries that source males from natural habitats to provide milt for egg fertilization, and the pituitary gland for induced breeding. Sourcing of male brood stock is not based on any clear guidelines, and brooders are often obtained from a different drainage basin, or a different population of C. gariepinus. This could be creating conditions similar to hatcheries that introduce new brood stock from different populations of a fish species to increase genetic variation after several generations of repeated breeding of same individuals. Multiple introductions of different gene pools are often undertaken by hatcheries as a strategy for restoring and maintaining high genetic variation in hatchery reared fish stocks (Van der Bank et al. (1992); Hedrick \& Kalinowski, 2000; Wachirachaikarn et al. (2009). However, among the natural populations, LBA had a lower number of alleles ( $3.80 \pm 0.84$ ), compared to other natural populations. This could be attributed to a recent colonization of the lake by $C$. gariepinus, after the lake witnessed frequent drying during the Holocene (Verschuren et al., 2000), especially given its shallow depth (maximum depth 2.1 m ) and small surface area of $130 \mathrm{~km}^{2}$ (Beadle 1974; Bessem et al., 2008). Empirical evidence
shows that Lake Baringo was completely dry about 200 years ago (Bessem et al., 2008). Therefore the Lake Baringo population of C. garienus would be evolutionarily youger than the Lakes Victoria and Turkana and Kanyaboli populations. Lower genetic variation is reported in fish with recent colonization history than older and more stable lineages (Barluenga \& Meyer, 2010). Although both LTA and LBA are located in the eastern Rift, LTA reported a higher number of alleles and therefore higher genetic variation than LBA, because of a historical connectivity with the Western Nile (Dumont, 1986). Rifting cut off this connectivity, but LTA population retained higher genetic diversity extant in the Nile system, while LBA was seeded by the Kanguen River after re-filling in the late Holocene (Dumont, 1986; Bessem, et al., 2008). Higher genetic variation in LTA compared to LBA could not be revealed by mtDNA since this is a single locus, as opposed to the multi-locus microsatellite DNA markers.

Except for LBA, the number of alleles and $\mathrm{H}_{E}$ among natural catfish populations were uniform, while both the number of alleles $(\mathrm{Na})$ and $\mathrm{H}_{E}$ varied strongly among samples from fish farms. This could be attributed to genetic drift in farmed samples, since fish farms usually hold small sample sizes of fish, which are used for both propagation and grow-out. This is consistent with the results of Hansen et al., (2006), where strong variation in both Na and $H_{E}$ among farmed samples of the Indian major carp occur due to genetic drift in samples, related to breeding practices. While male brood stock are sacrificed for milt and pituitary, females of preferred features and sizes (200 to 500 g ) are re-used in artificial propagation, after a reconditioning period of 2-3 months. A re-use of brood stock favors certain traits whose allele frequencies increase at the hatchery, at the expense of traits in brooders that are not used, whose alleles are lost.

On the other hand, LVG, LKG and LTA showed less variable number of alleles and $H_{E}$, which were much higher than for LBA. Historical connectivity of Lake Victoria to the western arm of the rift, sharing ichthyofauna with Lakes Kyoga, Albert and George before it was uplifted to $1,000 \mathrm{~m}$ by tectonic uplifting (Beadle, 1974; Partridge et al., 1995) could explain higher genetic variation in LVG. This diversity in genetic variability could have been maintained by the large size of the L. Victoria water mass (Barasa et al., 2014), despite predation of LVG by the exotic L. niloticus. Similarly, Lake Turkana was connected to the Nile drainage system, before it was cut off by rift (Dumont, 1986), and hence the high genetic variation of the population could be a reflection of historical diversity of C. gariepinus in the Nile.

The inbreeding coefficient showed that samples of LKG, SAG, UoE and KIB $C$. gariepinus were inbred, while LVG, LTA, LBA and SAN were not. Of the four inbred populations, only one was natural, with the rest being farmed. Inbreeding in farmed catfishes could be attributed to effects of domestication, where hatchery operators select good looking brooders (females as a source of eggs, and males for milt and pituitary hormone). This selection favours certain genotypes, which are used for propagation, and eliminates others that are considered less desirable for propagation. Also after propagation, female brooders are re-used to spawn eggs in the next propagation, after a reconditioning period of 2 to 3 months. Furthermore, some of the progeny from the brooders are retained on the farms to boost the numbers of brood stock, and so are used as male and female brooders in subsequent generations. This increases the likelihood of progeny sharing alleles by virtue of being identical by descent, and constitutes inbreeding (Norris et al., 1999), which leads to inbreeding depression. Inbreeding in farmed populations is reported not only in catfishes (Van Der Walt et al., 1993; Popoola et al., 2014), but also in other farmed species such as
the Atlantic salmon, Salmo salar (Su et al., 1996; Bourret et al., 2011; Perrier et al., 2014), and tilapias (Eknath \& Hulata, 2009). Additionally, inbreeding in farmed samples of C. gariepinus could result from small numbers of brood stock that farmers usually maintain at hatcheries and farms. Keeping small numbers of brooders is a common practice among C. gariepinus farmers because of limited facilities (ponds and tanks), and difficulties of catching and transporting large numbers of live catfish brooders from natural habitats to farms. Furthermore, the number of brooders kept at the farm often reduces naturally over time, because of cannibalism among the brooders kept in the same pond or tank, especially if the fish are inadequately fed, using poor quality diets.

On the other hand, inbreeding in the natural population of LKG, could be attributed to the small size of the lake (Barasa et al., 2014), which could easily cause genetic drift in the population. Similarly high fishing pressure in Lake Kanyaboli (LKG) (Aloo, 2003), to provide catfish for both food and bait for L. niloticus (Barasa et al., 2016) could be causing inbreeding in the population by reducing the population size of the fish. Inbreeding is also reported in natural populations of other fish species such as salmonids (Wang et al., 2002; Perrier et al., 2014).

### 5.2. Population Genetic structure of C. gariepinus inferred from mitochondrial D-loop control region and Microsatellite DNA data.

There was differentiation among populations, as illustrated by significantly different $F_{\text {ST }}$ values ( $\mathrm{p}<0.05$ ), in a total of 28 pair wise comparisons in mtDNA and 15 pair wise comparisons in microsatellite DNA analyses. Therefore, differences in the populations could be attributed to among population genetic variation. Differentiation among populations could be due to geographic isolation, of the main populations.

According to Beadle (1974), and Giddelo et al., (2002), rifting caused the elevation of Lake Victoria on to an uplifted plateau ( $1,000 \mathrm{~m}$ above sea level), separating it from the connectivity with the western rift. Although both Lakes Baringo and Turkana are in the old eastern or Gregory rift, Lake Turkana and the Omo river were separated from the Nile River system less than 10,000 years ago (Dumont, 1986), when the Kanguen river became affected by tectonic uplifting (Beadle 1974). High genetic differentiation among populations of C. gariepinus is reported by Giddelo et al., (2002); Roodt-Wilding et al., (2010); Ojiambo, (2015) and Barasa et al., (2017). The results of this study indicate that gene flow is restricted to samples of C. gariepinus from fish farms (UoE, KIB, WKU, SAN and SAG), which are translocated around the country, as sources of seeds, or brood stock. This is so especially for the LVG population, from which most farmed populations except SAG were derived. Similarly, gene flow among the populations could be attributed to the trade in live $C$. gariepinus bait samples (Barasa et al., 2014), where bait traders collect catfish fry from both farms and natural aquatic habitats (such as Lake Kanyaboli) for sale to fishermen along landing beaches of Lake Victoria daily for catching L. niloticus by long lines. During the fixing of the bait samples onto hooks by L. niloticus fishermen, some of the live samples could escape into the waters of Lake Victoria. Also, some of the samples on the hooks could wriggle off and escape into the water, leading to gene flow.

However, of the 5 clusters identified in the samples (Fig. 4.2), samples from Sagana Aquaculture Center were the only samples from fish farmes that formed a distinct cluster of its own. This showed that the C. gariepinus broodstock at Sagana formed a population, while samples from all the other farms sampled did not form a population. This reflects the uniqueness of SAG population, which could be attributed to possible
multiple introductions of C. gariepinus from different sites to the farm. Multiple introductions of fish gene pools to a hatchery are known to increase genetic variability of brooders (Van De Bank et al., 1992; Grobler et al., 1997). However, results of this study are not able to tell specific sites from which some of the brooders of SAG were collected from, since field sampling for tis study did not include any samples from around Sagana Aquaculture center.

From the analysis of population genetic structure by STRUCTURE (Fig. 4.4) and STRUCTUREHARVESTER (Fig. 4.5) softwares, it was found that the samples clustered into 4 populations of C. gariepinus: LVG, LTA, LBA and SAG. The genetic structuring observed among the first three populations, which are natural populations, could be attributed to geographical separation of the water masses, due to volcanicity and tectonic activity, leading to genetic distinctness of the populations. Although the three lakes belong to the eastern rift (Giddelo et al., 2002), uplifting of Lake Victoria to a plateau (Partridge et al., 1995) disconnected it from Nile system and therefore also Lake Turkana (Giddelo et al., 2002). Further rifting disconnected Lakes Baringo and Turkana, and this led to distinct populations. These populations represent important Catfish genetic resources, which could be utilized in a genetic improvement programme for desirable traits, as recommended by Ponzoni \& Nguyen, (2008).

### 5.3. Life-history parameters of Clarias gariepinus from Lakes Victoria, Baringo and Kanyaboli populations of Kenya

### 5.3.1. Relative fecundity

Relative fecundity, the number of eggs per gram body weight spawned by a fish (Bagenal \& Tesch, 1978), is an important parameter in both fisheries and aquaculture. A higher relative fecundity would typically be desirable as it increases persistence and
resilience of the population in the fishery despite fishing pressure (Karjalainen et al., 2015). In aquaculture, a higher relative fecundity increases seed availability for restocking ponds in the enterprise, and also for sale to other fish farmers. In the current study, samples of LVG population had a higher relative fecundity than both LBA and LKG, which had similar relative fecundity, despite LKG having a higher heterozygosity than LBA. High plasticity occurs in fecundity as a phenotypic trait (Karjalainen et al., 2015), and this variation can be both intraspecific and interspecific (Murua et al., 2003). Variability in fecundity of C. gariepinus populations has been reported in Ethiopia, with the Lake Chamo population (Dadebo et al., 2011) showing a higher fecundity than the L. Awassa population (Dadebo et al., 2000). In the current study, similar relative fecundity of LKG and LBA despite LKG having a higher heterozygosity could be attributed to a higher fishing pressure in Lake Kanyaboli than Lake Baringo. Overfishing is reported in Lake Kanyaboli (Aloo, 2003), and despite lack of information on Lake Baringo, fishing pressure is likely to be higher in Lake Kanyaboli than Baringo. High predation pressure (Reznick et al., 2004) and fishing pressure (Karjalainen et al., 2015) select for earlier and smaller size at maturity. Additionally, Lake Kanyaboli has a smaller watermass compared to both Lakes Baringo and Victoria (Barasa et al., 2017), and so the LKG population was probably smaller than both LBA and LVG populations. Individuals of a smaller population would be distributed over smaller spatial areas (Einum et al., 2003), and since fishing naturally targets bigger and therefore fish of a higher fecundity, this reduces the fecundity of the population. Since fecundity is related to size of the spawner (Kant et al., 2016), fish samples from Lake Kanyaboli probably reach sexual maturity earlier, and so spawn a fewer number of eggs.

Since LVG also had a higher heterozygosity than both LKG and LBA, and nutrient values were similar in the three habitats, the results seem to suggest an association between heterozygosity and relative fecundity as a life history trait in C. gariepinus. Therefore the LVG population seems to have a higher reproductive ability than both LBA and LKG, and lower heterozygosity in the evolutionarily younger LBA seems to reduce the reproductive ability of the population. Fecundity is a function of both genetic characteristics (Quattro \& Vrijenhoek, 1989; Danzmann et al., 1989; Liskauskas \& Ferguson, 1990) and environmental factors (Karjalainen et al., 2015; Vrtilek \& Reichard, 2016; Kant et al., 2016). The impact of genetic variation on fitness traits has been demonstrated in salmonids (Wang et al., 2002), in which inbreeding that erodes genetic diversity in a number of salmonids such as the Chinook (Onchorynchus tshawytscha), Coho (O. kisutch), Chum (O. keta) and the Atlantic salmon (Salmo salar) has reduced the survival rates of wild populations, prompting the species and populations to be listed under the endangered category in the USA (Knudsen et al., 2000; NRC, 2002). These studies highlight the importance of genetic variation as a primary genetic goal in conservation biology (Loeschcke et al., 1994; Allendorf \& Waples, 1996), since it influences complex life histories that ensure persistence of salmonid species in the environment (NRC, 1996; Policansky \& Magnuson, 1998), and may be exploited to increase production of farmed fish species such as $C$. gariepinus (Barasa et al., 2016; 2017).

### 5.3.2. Size at first maturity ( $\mathrm{L}_{\mathrm{m}} 50$ )

It is generally known that evolutionary changes in life history traits affect the viability and future harvests of a fishery (Heino, 1998; Hard et al., 2008). One such trait is the size at first maturity $\left(\mathrm{L}_{\mathrm{m}} 50\right)$ of a fish population. In the current study, LBA had both
sexes of fish maturing at a bigger size than both LVG and LKG. Both sexes of LVG had higher $\mathrm{L}_{\mathrm{m}} 50$ than for LKG. Size at first maturity, one of the most variable fitness traits, especially in fish species (Meyer et al., 2003; Hard et al., 2008; Feiner et al., 2017), is an attribute of genetic variability in populations (Thrower et al., 2004; Hard et al., 2008; Feiner et al., 2017), habitat quality and productivity (Meyer et al., 2003) and fishing pressure (Meyer et al., 2003; Hard et al., 2008). The results of this study do not reflect HFC hypothesis, since LBA of lower heterozygosity had higher values of $\mathrm{L}_{\mathrm{m}} 50$ than LVG and LKG, both of which had higher heterozygosity than LBA. This could be attributed to higher fishing pressure on LVG and LKG populations of C. gariepinus than LBA, which could have induced evolutionary pressure in favour of early maturing fish. Fish in populations under high predation pressure or fishing pressure mature earlier (Vrtilek \& Reichard 2016), and this reduces the asymptotic body size, since energy is reallocated from growth to reproduction (Kozlowski, 1992; Heino \& Kaitala, 1999; Quince et al., 2008). Higher fishing pressure also removes the bigger fish from the fishery, and induces changes that lead to precocious parents, maturing earlier (Gross, 1996; Locham et al., 2016), and this also reduces fecundity (Hamon et al., 2000; Hamon \& Foote, 2005).

High fishing pressure is reported in Lakes Victoria (Pringle, 2005; Turyaheebwa, 2014; LVFO, 2015) and Kanyaboli (Aloo, 2003), although no studies exist comparing fishing pressure in the three lakes. A lower fishing pressure may be expected in Lake Baringo than Lakes Victoria and Kanyaboli, since fishing in Lake Baringo is less commercialized, with fewer vessels and fishermen. Therefore, the results of this study seem to suggest that ecological factors may have a higher impact on $\mathrm{L}_{\mathrm{m}} 50$ than
genetic factors. However, genetic characteristics of C. gariepinus may be expected to influence $\mathrm{L}_{\mathrm{m}} 50$, if ecological factors are constant or comparable in different habitats.

## CHAPTER SIX

## CONCLUSION AND RECOMMENDATIONS

### 6.1. Conclusion

From mitochondrial D-loop data that investigated genetic variation in 10 populations of C. gariepinus, a total of five populations or clusters were detected. These included LVG, LTA, LBA, LJP and SAG, revealed by both the Maximum likelihood tree and the Minimum spanning network. But a total of four clusters of C. gariepinus were detected in the microsatellite DNA analysis, which included only samples from 8 sampling sites. Therefore, it is possible that up to five clusters of C. gariepinus could be detected also by microsatellite analysis if LJP and WKU samples were included in the study. Generally, high genetic variation was detected in the samples of $C$. gariepinus. Natural populations of the species had higher genetic variation than farmed samples, and this was revealed by both markers.

Gene flow occurred among populations of C. gariepinus, and was mainly restricted to samples from the Lake Victoria basin. This showed that gene flow was promoted mainly by translocation of fish by human activities for aquaculture, since the Lake Victoria basin is a main aquaculture region in the country. This was because most farmed populations had shared haplotypes, and natural populations that were located in isolated and far flung and dry areas (LTA ad LJP), where aquaculture was not practiced, did not have any shared haplotypes.

LTA and LVG had higher genetic variation than LBA, consistent with the fact that LTA and LVG are evolutionarily older lineages than LBA which is younger. Therefore, it appears that genetic variation in C. gariepinus increases with evolution, as expected from theory. LVG had higher relative fecundity than LBA and LKG, suggesting that heterozygosity seems to correlate with relative fecundity as a fitness
trait in C. gariepinus, although other factors like fishing pressure and inbreeding may erode the potential for high fecundity in the species. There was no correlation between heterozygosity and size at first maturity for the species.

### 6.2. Recommendations

Following the results of this study, the following recommendations are advanced:

1. Farmers may benefit from higher production if they use brood stock of $C$. gariepinus of higher genetic variation and distinctness in artificial propagation at hatcheries. However, comparative growth and survival of populations of higher genetic variation (LVG, LTA and LKG) and those of lower genetic variation (LBA) should be tested, to establish if growth and survival also correlate with genetic variation in C. gariepinus.
2. Interbasin transfer of C. gariepinus brood stock and fingerlings should be avoided, to ensure that genetically distinct populations are not homogenized by admixture, or introduction of new alleles or haplotypes.
3. The unique haplotypes and alleles should be conserved, by recruiting these populations into aquaculture.
4. Future research directions should focus on the relationship of heterozygosity and fecundity and size at first maturity in the face of differential environmental factors and fishing pressure.

Appendix XI: Gel electrophoresis of genomic DNA for Clarias gariepinus of the Lake Victoria (LVG) population. The genomic DNA was electrophoresed in $\mathbf{0 . 8 \%}$ agarose gel at 100 W for 35 minutes.

Appendix XII: Gel electrophoresis of purified PCR products for Clarias gariepinus from Sangoro Fish Farm (SAN), Kenya. The products were electrophoresed in $2 \%$ agarose gel at 100 W for 35 minutes. The size of the products, as determined by the DNA ladder ( L ) is 500 b

Appendix XIII: The length, weight, sex of fish, gonadal maturity stage, weight of gonads, gonado-somatic index (GSI), number of eggs per gram of eggs, and fecundity of fish samples of LVG population in September 2016.
